CONTENTS

CHAPTER XXXII

BORON

§ 1. The History of Boron (1); § 2. The Occurrence of Boron (3); § 3. Boron (7); § 4. The Borides (23); § 5. The Hydrides of Boron or Hydroborons (33); § 6. Boron Oxides (39); § 7. Boron Trioxide, Boric Oxide, or Boric Anhydride (41); § 8. The Boric Acids (47); § 9. The Alkali and Ammonium Borates (65); § 10. The Borates of Copper, Silver, and Gold (84); § 11. The Borates of the Alkaline Earths (85); § 12. The Borates of Beryllium, Magnesium, Zinc, Cadmium, and Mercury (95); § 13. The Borates of Aluminium, Thallium, and the Elements of the Rare Earths (102); § 14. The Borates of Tin, Lead, and Zirconium (105); § 15. The Borates of Arsenic and Chromium Families (107); § 16. The Borates of Manganese and of the Iron and Platinum Families (111); § 17. Perboric Acids and the Perborates (115); § 18. Boron Fluoride (121); § 19. Hydrofluoboric and Boratofluoric Acids (123); § 20. The Fluoborates (125); § 21. Boron Trichloride (129); § 22 Boron Tribromide (134); § 23. Boron Tri-iodide (135); § 24. Boratochlorides, Boratobromides, and Boratoiodides (137); § 25. Boron Sulphides (142); § 26. Boron Sulphates (146); § 27. Boron Phosphates (147).

CHAPTER XXXIII

ALUMINIUM

§ 1. The History of Aluminium (148); § 2. The Occurrence of Aluminium (153); § 3. The Preparation and Production of Aluminium (160); § 4. The Physical Properties of Aluminium (173); § 5 The Chemical Properties of Aluminium (202); § 6. The Atomic Weight and Valency of Aluminium (227); § 7. Alloys and Intermetallic Compounds of Aluminium (229); § 8. The Occurrence of Aluminium Oxides (247); § 9. Aluminium Oxides (253); § 10. The Properties of Aluminium Oxide (263); § 11. Aluminium Hydroxides, and Peroxides (273); § 12. The Aluminates (284); § 13. Aluminium Fluoride (300); § 14. The Fluoaluminates (303); § 15. Aluminium Chloride (311); § 16. Aluminium Bromide (324); § 17. Aluminium Iodide (327); § 18. Aluminium Sulphides (329); § 19. Aluminium Sulphates (332); § 20. The Complex Salts of Aluminium Sulphate (340); § 21. Aluminium Carbonates (358); § 22. The Aluminium Nitrates (359); § 23. The Aluminium Phosphates (362).

CHAPTER XXXIV

GALLIUM

§ 1. History of Gallium (373); § 2. The Occurrence of Gallium (374); § 3. The Extraction of Gallium (375); § 4. The Physical Properties of Gallium (377); § 5. The Chemical Properties of Gallium (380); § 6. Gallium Oxides and Hydroxides (382); § 7. Gallium Halides (383); § 8. Gallium Sulphides, Sulphates, and Nitrates (384).

CHAPTER XXXV

INDIUM

§ 1. The History and Occurrence of Indium (387); § 2. The Extraction of Indium (388); § 3. The Physical Properties of Indium (390); § 4. The Chemical Properties of Indium (393); § 5. The Oxides of Indium (397); § 6. Indium Halides (399); § 7. Indium Sulphides (403); § 8. Indium Sulphates (404); § 9. Indium Carbonate, Nitrate, and Phosphate (405).

CHAPTER XXXVI

THALLIUM

§ 1. The History and Occurrence of Thallium (406); § 2. The Extraction of Thallium (408); § 3. The Physical Properties of Thallium (410); § 4. The Chemical Properties of Thallium (419); § 5. The Alloys of Thallium (425); § 6. Thallium Oxides (430); § 7. Thallium Fluorides (436); § 8. Thallium Chlorides (438); § 9. The Thallium Bromides (450); § 10. Thallium Iodides (458); § 11. Thallium Sulphides (462); § 12. Thallium Sulphates (465); § 13. Thallium Carbonates (471); § 14. Thallium Nitrates (472); § 15. Thallium Phosphates (477).

CHAPTER XXXVII

SCANDIUM

§ 1. The History and Occurrence of Scandium (480); § 2. The Extraction of Scandium (482); § 3. The Properties of Scandium (485); § 4. Scandium Oxide and Hydroxide (488); § 5. Scandium Halides (488); § 6. Scandium Sulphide and Sulphate (491); § 7. Scandium Carbonate, Nitrate, and Phosphate (492).

CHAPTER XXXVIII

THE RARE EARTHS

§ 1. The Rare Earths (494); § 2. The History of the Rare Earths (496); § 3. The Occurrence of the Rare Earths (507); § 4. Fractional Precipitation, and Fractional Crystallization (538); § 5. The General Separation of the Rare Earth Group into Chemical Individuals (548); § 6. The Processes Employed in Resolving the Rare Earths into their Component Earths (556); § 7. The Occurrence and Isolation of the Cerium Family of Rare Earths (586); § 8. The Preparation of the Metals of the Cerium Family (589); § 9. The Physical Properties of the Cerium Family of Metals (591); § 10. The Chemical Properties of the Cerium Family of Metals (601); § 11. The Valency of the Rare Earth Metals, and their Position in the Periodic System (612); § 12. The Atomic Weights of the Cerium Family of Metals (621); § 13. The Oxides of the Cerium Family of Earths (625); § 14. The Halides of the Cerium Metals (637); § 15. The Sulphides of the Cerium Metals (648); § 16. The Sulphates of the Cerium Metals (650); § 17. The Carbonates of the Cerium Metals (664); § 18. The Nitrates of the Cerium Metals (668); § 19. The Phosphates of the Cerium Metals (675); § 20. Yttrium (676); § 21. The Terbium Family of Rare Earths (686); § 22. The Compounds of the Terbium Earth Metals (692); § 23. The Erbium Family of Rare Earths (696); § 24. Compounds of the Erbium Earth Metals (702); § 25. The Ytterbium Family of Earths (705).

CHAPTER XXXIX

CARBON

§ 1. The History of Carbon (700); § 2. The Occurrence of Carbon (715); § 3. The Different Forms of Carbon—Allotropy (718); § 4. The Action of Heat on the Diamond and Graphite (724); § 5. The Synthesis and Genesis of Diamonds (730); § 6. The Genesis of Graphite (738); § 7. The Preparation of Amorphous Carbon (744); § 8. The Physical Properties of the Different Forms of Carbon (755); § 9. The Adsorption of Gases, etc., by Carbon (789); § 10. The Action of Oxygen and Water on Carbon (811); § 11. The Chemical Properties of Carbon (821); § 12. The Constitution, Valency, and Atomic Weight of Carbon (837); § 13. The Carbides—The Alkali Carbides (844); § 14. The Carbides of the Copper Family of Elements (850); § 15. The Carbides of the Alkaline Earths (856); § 16. The Carbides of the Magnesium-Zinc Family (866); § 17. The Carbides of Aluminium and the Rare Earth Metals (870); § 18. The Carbides of the Silicon and Tin Families of Elements (875); § 19. Carbides of the Nitrogen, Vanadium, and Chromium Families of Elements (887); § 20. The Carbides of Manganese, and of the Iron and Platinum Family of Elements (892); § 21. The Carbon Oxides and Suboxides (904); § 22. The History of Carbon Monoxide (907); § 23. The Occurrence and Preparation of Carbon Monoxide (909); § 24. The Physical Properties of Carbon Monoxide (915); § 25. The Solubility of Carbon Monoxide (923); § 26. The Chemical Properties of Carbon Monoxide (926); § 27. The Metal Carbonyls (950); § 28. The Carbonyl Halides (962); § 29. Carbonyl Sulphide (971).

INDEX 979

ABBREVIATIONS

aq. = aqueous

atm. = atmospheric or atmosphere(s)

at. vol. = atomic volume(s)

at. wt. = atomic weight(s)

T° or °K = absolute degrees of temperature

b.p. = boiling point(s)

θ° = centigrade degrees of temperature

coeff. = coefficient

conc. = concentrated or concentration

dil. = dilute

eq. = equivalent(s)

f.p. = freezing point(s)

m.p. = melting point(s)

mol(s) = $\left\{\begin{array}{l}\text{gram-molecule(s)}\\ \text{gram molecular}\end{array}\right.$

mol(s). = $\left\{\begin{array}{l}\text{molecule(s)}\\ \text{molecular}\end{array}\right.$

mol. ht. = molecular heat(s)

mol. vol. = molecular volume(s)

mol. wt. = molecular weight(s)

press. = pressure(s)

sat. = saturated

soln. = solution(s)

sp. gr. = specific gravity (gravities)

sp. ht. = specific heat(s)

sp. vol. = specific volume(s)

temp. = temperature(s)

vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**, 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances A, B, and C, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle ternary mixture. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the standard of reference, the point *A* represents 100 per cent. of *A* and nothing else, mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig 4 results. Any point in this diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER XXXII

BORON

1. The History of Boron

UNDER the name *tincal* or *tincar*, the salt *borax* was exported to Europe from Central Asia, through Constantinople and Venice. It is not known when the trade began, but it must have been before G. Agricola,[1] since borax was much used in his time—1556. According to J. G. Wallerius, the Arabian Avicenna first described tincar. From G. Agricola's descriptions it is evident that his "chrysocolla which the Moors call *borras*" was the same salt as that now called borax. F. Hoefer says that the word *borax* is derived from an Arabian or Persian word *borak*, meaning white. The Arabians—*e.g.* Avicenna, Almas'adi, Madoyas, Alhabib, Dschabir Ibn Hajjan, Ibn Hauqual, etc.—some of the Greek alchemical writers—*e.g.* Joannis in his *De arte sacra*—as well as the chemists of the Middle Ages—*e.g.* A. Libavius, A. A. Barba, etc.—seem to have included several different salts—nitrum, natron, and borax—under the term *bauracon*, *borach*, *baurak*, or *baurach*; and when it was found that baurach is quite different from nitre, the term was reserved in Europe for the one particular salt "which first came from Tibet and India," and the word was soon modified into the present-day term borax. The term *baurax* is used by Raymund Lully, and *baurach* by Roger Bacon. G. Agricola was wrong in many of his statements about borax. He said that the *chrysocolla*—*chrysos*, gold; *colla*, solder—of the ancients was borax.

A spurious work attributed to Aristotle, but thought by J. Ruska, and E. O. von Lippmann to have been written in the ninth century, refers to the use of *nitron* as a flux, and for soldering. F. Freise reported the discovery at Delos of a crucible used for gold melting, which appeared to have once contained molten borax. The presence of boriferous minerals in Asia Minor also indicates the possibility that borax may have been known in the East. In the first century of our era, Pliny referred several times to *chrysocolla*, which he confused with gold solder, a copper ore, and a green pigment. G. Agricola seems to have based an opinion on Pliny's statement that *chrysocolla*—used as a solder for gold and silver—was made from verdigris, nitrum, and urine; and he argued that since borax is used in soldering gold, the two substances must be the same. G. Agricola said:

> Native *nitrum* is found in the earth or on the surface. . . . It is from this variety that the Venetians make *chrysocolla*, which I call *borax*. . . . The second variety of artificial *nitrum* is made at the present day from the native *nitrum*, called by the Arabs *tincar*, but I call it usually by the Greek name *chrysocolla*; it is really the Arabic borax. This *nitrum* does not decrepitate nor fly out of the fire; however, the native variety swells up from within.

G. E. Stahl emphasized that the Venetians did not make borax, but rather purified crude tincal. This confusion in the meaning of the word prevailed up to the seventeenth century. Paul de Canotanto, who lived in the middle of the fifteenth century, referred to the different kinds of borax, and stated that one variety was used in fusing, and in soldering the metals. Some extraordinary guesses were made near the beginning of the eighteenth century as to the nature of borax. J. Zwelfer regarded it as a natural fixed alkali; G. Homberg, as a *sel urineux mineral*; and J. J. Becher, as a compound of the universal acid with a vitrifiable earth. The confusion was partly the result of observations on the impure tincal which gave on distillation or combustion empyreumatic and ammoniacal products derived from organic impurities which were not recognized as accidental and foreign to the salt, but were considered to be inherent constituents of borax.

From the behaviour of borax towards alkalies and acids N. Lemery, in 1703, inferred that it contained a *sel salé*. G. E. Stahl (1702), and H. Boerhaave (1732) classed borax among the mineral acids. In 1702, G. Homberg heated borax with ferrous sulphate, and obtained a product, boric acid, which, on account of its medicinal properties, was designated *sal sedativum*, and it came to be called *le sel sédatif de Homberg*, although G. Homberg himself gave *sal sedativum—sedative salt*—many names—*e.g.* he called it *sel volatil narcotique de vitriol, sel volatil de borax, fleurs de vitriol philosophique, sel blanc des alchimistes*, and *fleurs de Diane*, for he regarded it as a compound of ferrous sulphate. L. Lemery (1728) showed that *sal sedativum* could be obtained by treating borax with acids in place of ferrous sulphate, and C. J. Geoffroy (1732) decomposed borax with sulphuric acid, and obtained (i) *le sel sédatif* in the form of white crystals, and (ii) Glauber's salt. J. F. Henkel had previously obtained an analogous result in 1722. C. J. Geoffroy added:

> Je pouvais donc conclure que le sel de la soude a beaucoup d'analogie avec le borax, puisqu'ils ont tous les deux une terre semblable à la terre du sel marin (soude), mais qu'il manque au sel de soude pour être parfaitement semblable au borax, la terre vitrifiable qui est dans ce dernier (boric acid).

J. H. Pott discovered the more salient properties of *sal sedativum*, but he did not advance our knowledge of the constitution of borax very far; he called it "a neutral salt composed of vitriol and borax." He found that the salt imparts a green colour to the flame of burning alcohol. This coloration led many later chemists to assume wrongly that copper is an essential constituent of borax. In 1747–8, T. Baron published two memoirs describing his *Expériences pour servir à l'analyse du borax*, and he there clearly described the nature of borax. He said that *sal sedativum* is always the same whatever be the acid employed to derive it from borax; that borax can be reproduced by mixing *sal sedativum* with a sodium salt; and that two other kinds of borax can be made by substituting a salt of potassium or ammonium in place of sodium. He showed that *sal sedativum* is not volatile, but that it does sublime when heated with water vapour. He regarded *sal sedativum* as a new substance, and showed that, at an elevated temp., it can drive the acid from potassium nitrate or from sodium chloride. In 1775, U. F. Hoefer discovered *sal sedativum Hombergii* in the waters of the Tuscan lagoons of Monte Rotondo and Castelnuovo, and found that when treated with mineral alkali, it formed borax; this gave him the idea of manufacturing borax from the waters.

In the light of present knowledge, T. Baron's conclusions seem a satisfactory proof that borax is "a compound of *sal sedativum* and the alkali of common salt," but his contemporaries were still puzzled, for, in 1761, L. C. Cadet raised some ill-founded objections to T. Baron's views, and stated his belief that borax contains copper, arsenic, and a vitrifiable earth; L. C. Bourdelin (1753) assumed that it contained a vitriolic acid; G. V. M. Fabroni, that it is a modification of muriatic acid; B. G. Sage, that phosphoric acid is present; and L. F. F. von Crell (1799), that it contains carbon. T. Bergman was clear enough as to the acid nature of *sal sedativum*. He said:

> The substance commonly called sedative salt is more nearly allied to acids than to any other class of bodies. It reddens litmus; and saturates alkalies and soluble earths. It also dissolves various metals, and has other properties which show its acid nature; and it seems better entitled to the name borax acid than to that of sedative salt.

With the introduction of anti-phlogistic chemistry, the nature of borax became clear; *sal sedativum* was recognised as an acid, and called *boric or boracic acid*. In August, 1807, H. Davy electrolyzed moist boric acid and obtained a dark-coloured combustible mass at the negative pole, and the following year he obtained a similar product by heating potassium with boric acid in a gold tube. Towards the end of 1808, he examined the properties of the dark product, and concluded "from all analogy, there is strong reason to consider the boracic basis as metallic in its nature, and I venture to propose for it the name of *boracium*." J. L. Gay Lussac and L. J. Thénard decomposed boric acid with potassium on the 21st of June, 1808. They said :

> Nous désignerons par le suite ce radical sous le nom de *bore*, qui est tiré de celui du borax, et nous désignerons l'acide boracique sous celui d'acide borique pour nous conformer aux principes des nomenclateurs. Ainsi nous aurons les trois expressions, *bore, borique, borate*, entièrement analogues aux trois autres, *carbone, carbonique, carbonate*.

A few years later, 1812, H. Davy also stated that boracium is more analogous to carbon than to any other substance, and hence proposed "*boron* as a more unexceptional name." In 1824, J. J. Berzelius demonstrated the proportion of oxygen present in boric acid. F. Fittica thought that he had transformed boron into silica, but C. Councler showed that the alleged transformation was due to a mal-observation.

§ 2. The Occurrence of Boron

Boron does not occur abundantly on the earth, but small quantities are widely distributed. F. W. Clarke and H. S. Washington estimate that the ten-mile crust, the hydrosphere, and the atmosphere of the earth contain 0·001 per cent. of boron. This element occurs in the form of boric acid and borates, and is an essential constituent of many silicate minerals—*e.g.* tourmaline and datolite. H. A. Rowland[1] says that boron is not revealed in the spectrum of the sun. J. Smithson, and H. Jay have discussed the occurrence of boric acid in nature ; and C. F. Rammelsberg, the general distribution of the borates. The native borates, borosilicates, borosulphate, chloroborates, and borophosphates are :

Sassolite, or *sassolin*, boric acid, H_3BO_3 ; *larderellite*, $(NH_4)_2B_8O_{13}.4H_2O$; *borax*, or *tincal*, $Na_2B_4O_7.10H_2O$; *borocalcite*, or *bechilite*, $CaB_4O_7.4H_2O$; *pandermite*, or *priceite*

$Ca_2B_6O_{11}.3H_2O$; *colemanite*, $Ca_2B_6O_{11}.5H_2O$; *boronatrocalcite*, or *ulexite*, $NaCaB_5O_9.6H_2O$; *cryptomorphite*, $H_2Na_4Ca_8(B_4O_7)_9.22H_2O$; *franklandite*, $CaNa_2B_6O_{11}.7H_2O$; *ascharite*, $3Mg_2B_2O_5.2H_2O$; *pinnoite*, $MgB_2O_4.3H_2O$; *boromagnesite*, or *szaibelyite*, $4BO_2(Mg.OH)$-$Mg(OH)_2$; *pinnoite*, $MgB_2O_4.3H_2O$; *kaliborite*, or *heintzite*, $K_2Mg_4B_{22}O_{38}.14H_2O$ or $KH_2Mg_2B_{11}O_{20}.6H_2O$; *hydroboracite*, $CaMgB_6O_{11}.6H_2O$; *boracite*, $Mg_7B_{16}O_{30}Cl_2$; *sulphoborite*, $4MgHBO_3.2MgSO_4.7H_2O$; *lüneburgite*, MgB_2O_4 $2MgHPO_4.7H_2O$; *hambergite*, $(Be.OH)BeBO_2$; *jeremejevite*, $AlO.BO_2$; *rhodizite*, $K(AlO)_2(BO_3)_2$; *pinakiolite*, $(Mg, Mn)_2O(BO_2)MnO_2$; *sussexite*, $(Mn, Mg, Zn)BO_2OH$; *lagonite*, $Fe(BO_2)_3.1\frac{1}{2}H_2O$; *ludwigite*, $Mg_2O(BO_2)(FeO_2)$; *datolite*, $Ca(B.OH)SiO_4$; *howlite*, $CaH_3(BO_2)_5.CaH_2SiO_4$; *bakerite*, $8CaO.5B_2O_3.6SiO_2$; *homilite*, $Fe\{Ca(BO)SiO_4\}_2$; *tourmaline*, or *schörl*, $(SiO_4)_2(AlO.BO)\{(AlO)_2(Mg, Fe, Na_2, Li_2, H_2)\}_3$.

E. Filhol found traces of borates in felspar from the Pyrenees, and in pegmatite from Aveyron ; E. Bechi, in Italian limestones, travertine, basalt, sandstone, etc. ; E. T. Wherry and W. H. Chapin, in vesuvianite ; L. Dieulafait, and C. Nöllner, in Chilian nitrate deposits ; J. B. J. D. Boussingault, in the crater of some volcanoes ; E. Filhol, and F. P. Venable and J. S. Callison in commercial caustic alkalies ; and T. Egleston, in the iron ores of Lake Superior. A. Lacroix and A. de Gramont spectroscopically examined the aluminosilicate minerals for traces of boron.

According to L. Dieulafait, G. Forchhammer, and C. Nöllner, borates are contained in sea-water, and in the ashes of marine plants. J. A. Veatch found boric acid in the water collected over a submarine ridge along the coast of California, and he suggested that it had a volcanic origin from submerged sources. The existence of borates in sea-water is exemplified by the borates of the Stassfurt deposits described by H. E. Boeke, and W. Biltz and E. Marcus. The Stassfurt borates boracite, pinnoite, ascharite, heintzite, hydroboracite, sulphoborite, lüneburgite, etc.- are essentially magnesian, in contrast with the Chilian and Californian deposits where calcium borates are dominant. In 1775, U. F. Hoefer reported *sal sedativum* (boric acid) in the waters of Monte Rotondo. Free boric acid also occurs in the crater of an extinct volcano in the Lipari Islands, and in the crater of Stromboli. Volcanic ejecta containing boric acid have been reported in Nova Scotia, and in Nevada, California. The *soffioni* or fumaroles of Pomerance, Massa Marittima, Castelnuovo di Val di Cecina, and Montieri, all in Tuscany, are an important source of boric acid ; jets of steam carrying boric acid emerge from the ground, and sassolite, larderellite, bechilite, and lagonite are deposited by the lagoons in which the vapours are condensed. The salts have been analyzed by C. Schmidt, and C. M. Kurtz. The average foreign matter in the Tuscan lagoon waters, in grams per litre, is: Total solids, 9·96 ; boric acid, 7·14 ; ammonium sulphate, 0·87. There is some relation between the ammonium salts and the boric acid. A. Lacroix likewise found ammonium chloride and boric acid in Vesuvian fumaroles ; A. Bergeat, in the volcanic products of Vulcano (Lipari Islands) ; G. F. Becker, and H. G. Hanks, in Borax Lake (Lake County, Cal.) ; in the water of the Devil's Inkpot (Yellowstone Park) ; and by E. Cortese, in the hot springs of Chaguarama Valley (Venezuela). This led to the hypothesis—R. Warington, H. St. C. Deville and F. Wöhler, O. Popp, E. Bechi, etc.—that the boric acid is derived from the action of steam on boron nitride. The latter, however, has not yet been observed as a mineral species ; and similar remarks apply to J. B. A. Dumas' hypothesis, adopted by A. Payen, that the boric acid is the result of the action of steam on boron sulphide, a reaction devised to account for the presence of hydrogen sulphide in the gases. P. A. Bolley suggested that the boric acid is a product of the action of ammonium chloride on borax ; E. Bechi, the action of steam and carbon dioxide, at 300°, on boriferous serpentine ; and E. Perrone, and R. Nasini, by the action of steam on tourmaline. The subject has also been discussed by G. d'Achiardi, H. St. C. Deville and F. Leblanc, F. Fouqué and H. Gorceix, and H. Coquand. The borates of Esmeralda County, Nevada, and of Inyo and San Bernardino Counties, in Death Valley, in the basin of the Amargosa River, etc.—*e.g.* Searles' Borax Lake—are represented by the predominant calcium salts, ulexite and colemanite, as well as by some borax.[2]

W. D. Dennis has described the borax deposits of Lake Alvord in Harney County, Oregon. Arid regions containing sodium nitrate occur near the borate deposits of South California and ulexite occurs near the nitre deposits of Tarapaca and Atacama (South America).[3] The calcium salt is the predominant borate in the deposits near Iquique, the Cordilleras of Coquimbo, and the Taltal district; and R. T. Chamberlin has noted that the borax lake of Ascotan derives its borates from the leachings from adjacent volcanoes. J. J. Kyle described the deposits in Salta and Catamarca; H. Buttgenbach, the Salinas Grandes, Province of Jujuy, Argentine; F. Reichert, the Argentine borates; and A. Jockamowitz, the Salinas Lagoon, Arequipa, Peru. W. S. Vernadsky and S. P. Popoff described the borax deposits near the Sea of Azov, Kerch peninsula. H. von Schlagintweit described the great borax deposits of Puga Valley, Ladak, Tibet. He said that the borax is a deposit from hot springs at a temp. between 54° and 58°, and situated over 15,000 feet above sea-level. The saline mass is said to contain free boric acid and sulphur, and a little salt, ammonium chloride, magnesium sulphate, and alum, but no ulexite. The Nova Scotia deposits, described by H. How, are supposed to be marine, but the total absence of magnesium is not in accord therewith, for, as F. W. Clarke has shown, marine deposits usually contain magnesium borates; lake-bed deposits contain calcium borates with nitrates near by, while borates from volcanic waters and fumaroles yield some ammonium compounds.

Small quantities of borates have been reported to occur in many mineral waters and springs—*e.g.* in Aachen, by R. Wildenstein[4]; at Wiesbaden, Schlangenbad, Krankenheil, and Weilbach (Nassau), by C. R. Fresenius, and G. C. Wittstein; at Schinznach and Bex (Switzerland), by S. Baup, and L. Dieulafait; at Vichy, etc., by H. Fonzes-Diacon and M. Fabre, where the amount increased with the temp. of the spring; at Salzmatt, by A. Béchamp, and L. R. Lecanu; at Sulbach, by C. Oppermann; at Rhodisfort, by H. Göttl; at Kissingen, by J. von Liebig; at Orb, by F. Rummel; at Soden (Spessart), by F. Moldenhauer; at Olette, by J. Bouis; at Bagnères-de-Luchon, Barèges, Cauterets, Bonnes, and Labanère in the Pyrenees, by E. Filhol; at Curset, Hauterive, St. Yorre, Vaisse, and Vichy by J. Bouquet; at Plombières, by O. Henry and M. Lhéritier; in most mineral waters of Central France, by F. Parmentier; at Montecatini (Tuscany), by L. Dieulafait; in North Africa, by L. Dieulafait; at White Island (New Zealand), by C. du Ponteil; in the mud volcanos of the Colorado District, San Diego County, as well as in the waters of several mineral springs in Tehama County, California, by J. A. Veatch; and in Rohat, by A. Carnot.

E. Hotter,[5] H. Agulhon, and H. Jay have discussed the occurrence of boric acid in the vegetable kingdom, and in various kinds of fruit; and A. H. Smith, in food stuffs. G. Baumert, P. Soltsien, J. Dugast, M. Bertainchaud and E. Gauvry M. Ripper, S. Weinwurm, A. Gassend, F. Schaffer, and E. Azzarello found boric acid normally present in wines; J. Brand, in hops, and hence also in beer; G. C. Wittstein and F. Apoiger, in the seeds of the *maasa picta;* E. O. von Lippmann, beet root; C. A. Crampton, water melon; E. Bechi, the beeches of Tuscany; A. Gassend, pepper; P. Kulisch, apples; E. Deltour, in almonds, molasses, chicory, acorns, mountain-ash berries, white wines, Bordeaux wines, and fruit syrups; apples, pears, currants, raspberries, and cherries. According to A. H. Smith, dates showed the largest proportion of boric acid, and prunes came next. The percentage amounts were: dates, 0·0299; dried peaches, 0·0065; dried apricots, 0·00216; prunes, 0·00792; figs, 0·0039; and raisins, 0·0049. Boric acid has also been found in parsnips, carrots, ranunculaceæ, radishes, angelica, and peonies; E. O. von Lippmann, and A. Hebebrand also reported boric acid in various fruit juices—lemons, oranges, etc. A. Gassend said boric acid is never found in tea, or saffron; but E. Deltour found it in fern leaves, tomatoes, ergot, potatoes, tobacco, straw, pepper, beer, vinegar, milk, vines, corn, coffee, and grass. E. Eckenroth, E. G. Clayton, E. Deltour, and A. Gassend said that boric acid is not a normal constituent of milk. E. Deltour found no boric acid in the bones of fowls, or in egg-shells.

K. Fischer found boric acid in many varieties of parchment. A. H. Smith found 0·00049 per cent. of boric acid in sausages; the salt in which the meat was cured contained 0·00045–0·00077 per cent. of boric acid. He added that these results show that in some of our common fruits, probably in meat, and certainly in common salt, there are minute though measurable quantities of boric acid occurring naturally. However, it does not seem probable that these amounts of boric acid could injure the persons eating the foods. G. Bertrand and H. Agulhon examined about thirty species of animals, and concluded that boron exists normally in very small proportions, 1 part in 100,000,000 parts of living matter. It is most abundant in animals of marine origin. It was detected in the hair, horns, bones, liver, and muscles.

§ 3. Boron

In 1808, J. L. Gay Lussac and L. J. Thénard [1] prepared impure boron by fusing boric acid, mixing the powdered vitreous product with potassium, and heating the mixture to redness in a tube of iron, copper, platinum, or glass. The product was boiled with dil. hydrochloric acid ; washed with water ; and dried at a gentle heat. According to J. J. Berzelius, if the glassy boric acid is not thoroughly freed from water, the reaction will be attended by detonation or spurting. The product is amorphous or colloidal, and as the potassium salt is removed by washing, the boron remains suspended in the water in so fine a state of subdivision that it runs through the filter paper, and, continued Berzelius, "it even dissolves in the water to which it imparts a slight yellow colour." The presence of salts or acids prevents the comminution of the boron in the water, and he therefore recommended washing the product with a soln. of ammonium chloride, and removing the latter with alcohol. B. Reinitzer, and R. Lorenz also showed that some solid boron hydride is formed in the process ; and H. Moissan added that if the operation is conducted in metal tubes—copper, iron, gold, or platinum—the metal is attacked and the product is correspondingly contaminated. H. Davy, and R. D. Thomson employed a similar process. In place of potassium as a reducing agent F. Wöhler and H. St. C. Deville used sodium in the presence of sodium chloride. H. Moissan analyzed the products obtained (i) by J. L. Gay Lussac and L. J. Thénard's process as well as (ii) by F. Wöhler and H. St. C. Deville's process and heated in vacuo ; (iii) the same after washing in boiling hydrochloric acid ; and (iv) after a prolonged treatment with water :

	B	H_3BO_3	K	Cu	Fe	Na	BH	H	H_2O	
(i) . .	44·10	17·80	14·4	12·5	5·80	—	—	—	4·9	= 99·50
(ii) . .	69·50	15·65	—		4·61	6·63	5·84	0·44	—	= 102·67
(iii) . .	71·97	13·50	—	—	5·04	3·89	5·28		—	= 99·68
(iv) . .	32·38	42·52	—	—	7·51	10·34	2·26	4·10	—	= 99·11

This shows that the products by these processes are very impure. According to N. A. Orloff, a sample of commercial boron contained glassy granules of boric oxide, a little iron, and 9·07 per cent. of water corresponding with 20·83 per cent. of boric acid.

J. J. Berzelius reduced potassium borofluoride with potassium. F. Wöhler and H. St. C. Deville, and A. Geuther used magnesium ; according to H. Moissan, the product contains :

B	H_3BO_3	K	Fe	BN
51·15	23·07	6·00	3·06	8·75 = 92·03

J. W. Döbereiner claimed to have reduced calcined borax with carbon, but neither L. Gmelin, nor A. Pleischl were able to confirm this result; L. Gattermann, C. Winkler, F. Jones, T. L. Phipson, and H. C. C. Maisch reduced calcined borax or boric acid with magnesium; F. Wöhler and H. St. C. Deville, L. Franck, K. A. Kühne, O. Hönigschmid, F. E. Weston and H. R. Ellis, and H. Goldschmidt used aluminium as reducing agent; H. Moissan reduced boric oxide, or boron bromide or nitride with calcium, but A. Stock and W. Holle found the product is calcium boride not boron. A. C. Vournasos reduced the oxide with sodium formate; and G. Dragendorff reduced calcined borax with red phosphorus. H. N. Warren reduced a mixture of boric oxide and magnesium sodium chloride with sodium.

According to H. Moissan, when boric anhydride is heated with the theoretical quantity or an excess of magnesium, reduction takes place with formation of magnesium borides. The author finds that if the boric anhydride is in considerable excess different results are obtained. There are two magnesium borides, one unstable and decomposed by water with liberation of hydrogen and boron hydride, the other stable and not affected by water, hydrochloric acid, or nitric acid. To prepare amorphous boron, H. Moissan recommended the following process:

Seventy grms. of finely powdered magnesium, free from iron and silicon, were intimately mixed with 210 grms. of recently fused boric anhydride. The mixture was heated to bright redness in a clay crucible, and in a few minutes an energetic reaction took place. The central part of the product was boiled with water and hydrochloric acid until the magnesium borate was removed, then treated for a long time with successive quantities of pure boiling hydrochloric acid, washed with water, and with alcoholic potash, again washed with water, boiled for several hours with hydrofluoric acid, washed with water, and dried in a vacuum. The product is a very light maroon powder which does not alter when exposed to air; it contains 94 to 95 per cent. of boron, 2·3 to 3·75 per cent. of magnesium, and 1·2 to 1·6 per cent. of insoluble matter. If this product is fused with 50 times its weight of boric anhydride, and the product treated in the same way as the original product, a maroon powder is obtained containing only traces of magnesium. One product contained boron, 98·30; magnesium, 0·37; insoluble, 1·18 = 99·85. If the boron is required perfectly free from nitride, reduction must be effected in a crucible brasqued with a mixture of finely powdered titanic oxide and carbon; the product contains from 92·6 to 99·2 per cent. of boron. Boric anhydride may also be reduced by magnesium in porcelain dishes in an atmosphere of hydrogen, and a very pure product is obtained, but the yield is small.

A. Stock and W. Holle say that the product obtained by reducing boric acid with magnesium is always impure—86 per cent. of boron, and 8 per cent. of magnesium. G. Constant and V. Raisin made boron by the electrolysis of fused boric oxide made conductive by the addition of sodium chloride, alkali borate, etc. E. Podszus prepared boron by the reduction of boron trichloride by electrically heated iron wire. Reduction progresses at 800° and the temp. was raised to 1400°. The porous mass can be welded into a compact mass, and drawn into wire. The reduction of boron trichloride with sodium gave only a black powder which does not weld into a compact mass.

F. Ageno and E. Barzetti obtained a **colloidal solution** of boron by heating a mixture of boric anhydride with 25 per cent. of magnesium powder to redness; washing the cold powdered mass with warm dil. hydrochloric acid; boiling the product with conc. hydrochloric acid, and washing by decantation with water. A reddish-brown sol is formed which shows Tyndall's effect, and may be preserved some months. The colloid is negatively electrified; and it is precipitated by electrolytes. H. Kuzel has studied the peptization of colloidal boron.

J. J. Berzelius scrubbed gaseous boron fluoride in a tube containing crystallized boric acid, and in another tube containing lead dioxide to free it from silicon fluoride and sulphur dioxide. The boron fluoride was then reduced by passing it over heated potassium, which is first covered with a black crust and then burns with a red flame producing a mixture of boron and potassium fluoride. The latter is removed by washing. The boron thus prepared contained 0·4 per cent. of silicon. S. G. Rawson employed a similar reaction. J. B. A. Dumas claimed to have reduced hydrated boron chloride with hydrogen at a red heat; A. Besson and L. Fournier exposed a mixture of boron chloride and hydrogen to the silent electrical discharge; and H. Gustavson, distilled boron chloride over sodium at 150°. E. Weintraub reduced a mixture of the vapour of boron trichloride with hydrogen in a high-tension electric arc, between copper poles beneath the liquid or in the gas. The reaction was studied by J. N. Pring and W. Fielding, and by A. Besson and L. Fournier. F. Meyer and R. Zappner prepared it from boron bromide, which was boiled in a small bulb directly attached to a large bulb holding the electrodes, and this bulb was attached to a reflux condenser which returned the unattacked bromide to the vaporization flask. The tension of the current was 100,000 volts, and equilibrium was established in about five hours. A. H. Warth reduced boron trichloride with hydrogen in the presence of a glowing tungsten filament at 1300°–1850°, and obtained a deposit of boron of a high degree of purity.

B. Springfeldt obtained boron by heating the nitride, BN, to 1500° or 2000°; and A. C. Vournasos reduced the nitride by heating it with sodium formate, when amorphous boron, ammonia, and boron hydride are formed. A. Besson stated that in preparing boron iodide by the action of hydrogen iodide on H. St. C. Deville and F. Wöhler's amorphous boron, only a small portion is attacked, and he postulates that this represents a more *active variety of boron* than the remainder; but H. Moissan stated that this active boron is probably a mixture of iron and sodium borides.

H. Davy prepared impure boron by the electrolysis of moist boric acid. W. Hampe electrolyzed fused borax, and found that the sodium produced at the cathode immediately reduces the boric acid, forming boron. A carbon crucible was used with a platinum rod as anode, and a pencil of retort carbon as cathode. The product more or less crystalline is contaminated with carbon. H. Moissan, however, found that when a current of 35 amps. is passed through boric anhydride mixed with 20 per cent. of borax, and heated to 1200°, boron is liberated, but it immediately recombines with oxygen, with vivid incandescence. G. Gore, A. Stähler and J. J. Elbert, and A. Z. Hartmann have made some observations on this subject. E. Weintraub, and P. C. Ray showed that the amorphous boron prepared by H. Moissan's process contains several per cent. of oxygen; so also does the product obtained by the electrolysis of fused borax. As much as 16 per cent. oxygen has been reported. E. Weintraub also showed that in the magnesium reduction process, boron is easily obtained free from magnesium if a higher temp. be employed for the reduction than was the case in H. Moissan's experiments. P. C. Ray purified boron by heating to redness the amorphous powder with an excess of sodium or magnesium in a stream of hydrogen. In the former case magnesium boride is formed and decomposed. The product is extracted successively with water, hydrochloric acid, and warm 40 per cent. nitric acid. According to E. Weintraub, magnesium boride, nitride, and the product contaminated with oxide all decomposed when heated in vacuo, the change is appreciable at 1200°, and is rapid at 1500°. This dissociation enables the amorphous and less pure varieties of boron to be readily purified. E. Weintraub placed the powder in a water-cooled copper cup, which formed one electrode of an arc, the other electrode was of copper. The heating is conducted in vacuo or in hydrogen; and E. Tiede and E. Birnbräuer heated the impure boron by focussing the cathode rays on the powder. E. Weintraub also purified boron by compressing the powder into a rod *D*, Fig. 1, mounted in a

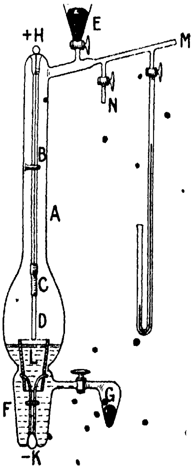

Fig. 1.—E. Weintraub's Mercury Arc Furnace.

carbon holder, *C*, to which a lead *B* is attached. This arrangement is placed inside a glass vessel *A*. The apparatus is filled with hydrogen *via M*, or evacuated *via N*. Mercury is introduced *via E* until the end of *D* is just covered; hydrogen is admitted to 2·5–15 cms. press., and the electrodes *H* and *K* connected to the source of current. Mercury is run into *G* until the end of *D* is just clear of mercury in the lower part of *F*. An arc is formed between the boron and the mercury in *F*. The end of *D* melts and falls off, and as the rod *D* shortens more mercury is run from *E* to maintain the arc. The bottomless alundum cup *L* serves to prevent the arc straying to the glass.

F. Wöhler and H. St. C. Deville reported the existence of black and yellowish forms of crystalline boron which they designated respectively *bore graphitöide*, and *bore adamantin*. They prepared the crystals in long prismatic needles by melting together boric anhydride and aluminium in a graphite crucible; and by packing a fireclay-crucible with amorphous boron, and inserting an aluminium rod in a hole bored in the powder. The crucible is then covered with its lid, and packed inside a larger crucible with powdered carbon. The whole is heated white hot. The boron dissolves in the molten aluminium, and crystalline boron separates out as the metal cools. F. Wöhler and H. St. C. Deville recognized that the crystals always contain carbon and aluminium, but they regarded the presence of these elements as accidental impurities. W. Hampe, and A. Joly have shown that these elements are essential constituents of crystalline boron. W. Hampe said the composition is $B_{48}C_2Al_3$. H. Biltz obtained $C_2Al_3B_{44}$ for the yellowish crystals. He separated them from the black crystals by flotation in a mixture of methylene iodide and benzene. A. Joly stated that among the products of the reduction of boric anhydride by aluminium in the presence of carbon, there are (i) golden-yellow hexagonal plates of aluminium boride, AlB_2, described by F. Wöhler and H. St. C. Deville and at one time thought to be graphitoidal boron; (ii) black plates of aluminium boride, AlB_2, described by W. Hampe; (iii) yellow quadratic crystals of adamantine lustre containing carbon and aluminium; and (iv) hard black crystals of a boron carbide, or more probably of several carbides, formed by the alteration of the preceding compounds at a high temp., in the presence of carbon and an excess of boric anhydride. The British Thomson-Houston Co. used the aluminium reduction process for preparing boron for the treatment of copper. K. A. Kühne prepared crystalline boron by heating boric acid with aluminium turnings and sulphur, and treating the cold mass with water. The aluminium sulphide is decomposed, while the crystalline boron remains intact. H. Biltz found the crystals to be aluminium boride, AlB_2.

The physical properties of boron.—Most of our knowledge of the physical properties of boron has been obtained from very impure samples. J. L. Gay Lussac and L. J. Thénard's[2] product was a dark greenish-brown or olive-green powder, without smell or taste. H. Moissan's amorphous boron is pale brown, greyish-brown, or a bright maroon-coloured powder which stains the fingers, and can be readily compressed into a cake. The powder is without any recognizable crystalline form. E. Weintraub's fused boron resembled black diamonds; it takes a good polish; and it has a conchoidal fracture with no recognizable microcrystalline form. F. Meyer and R. Zappner's boron was a fine deep black powder. J. L. Gay Lussac and L. J. Thénard's product sank rapidly when placed in conc. sulphuric acid. H. Moissan and A. Wigand gave 2·45, A. H. Warth, 2·3, and E. Weintraub, 2·34 for the **specific gravity**; E. Donath and J. Mayrhofer gave 0·373 for the sp. vol. J. L. Gay Lussac and L. J. Thénard said that boron does not scratch glass; actually, its **hardness** is rather less than that of the diamond, but it rubs off readily on the carborundum wheel. J. R. Rydberg placed its hardness as 9·5 on his scale. A. H. Warth said that boron is harder than sapphire; and is brittle. The **compressibility,** according to T. W. Richards, is $0{\cdot}3 \times 10^{-6}$ per atm. at 20°.

C. M. Despretz said that amorphous boron readily melts between the poles of a battery of 600 Bunsen's cells, and that the **melting point** is lower than that of silicon, and that its **volatility** is greater than that element, but J. L. Gay Lussac and

L. J. Thénard could neither melt nor volatilize amorphous boron at the strongest white heat available. E. Tiede and E. Birnbräuer melted boron in vacuo in a cathode ray furnace at 2200°. W. Guertler and M. Pirani gave 2400° for the m.p. of boron. W. R. Mott gave 2500° for an approximation to the m.p., and 2300° for the **boiling point**. F. Wöhler and H. St. C. Deville said that boron is slightly volatile at the m.p. of nickel, and that its colour changes by heating it to a very high temp. H. Moissan said that amorphous boron shrinks slightly, and increases in density when heated to 1500° in an atm. of hydrogen ; and that when placed in the electric arc, amorphous boron becomes red, and is surrounded by *une grande auréole verte*, but it shows no signs of fusion, and at the conclusion of the experiment, the ends of the carbon electrode have much boron carbide. E. Weintraub, however, showed that boron can be readily fused at atm. press. or in vacuo. E. Tiede and E. Birnbräuer gave 2200° for the m.p., and E. Weintraub, 2800°. Boron begins to vaporize below its m.p.; and the vap. press. is appreciable at 1200°. H. Kopp gave 0·254 for the **specific heat** of boron ; these numbers show that boron does not obey Dulong and Petit's rule as was observed by H. V. Regnault. H. Moissan and H. Gautier found the sp. ht. over 0°, and F. Koref below 0°, with the following results :

	−191° to −78°	−76° to 0°	0° to 100°	100° to 192·3°	192° to 234°
Sp. ht. . .	0·0707	0·1677	0 3066	0·3776	0·3443
At. ht. . .	0·778	1·838	3·372	4·153	4·766

The sp. ht. rises with temp., and by extrapolation, H. Moissan and H. Gautier infer that the at. ht. will be about 6·4 at 400°. A. Wigand, G. Schmidt, E. van Aubel, and F. Michaud have also discussed the question *vide* Fig. 7, **1.** 13, 12. According to L. Troost and P. Hautefeuille, the **heat of combination** of boron with oxygen is 14·42 Cals. per gram, or 158·6 Cals. per eq. ; M. Berthelot gave $(B, \frac{1}{2}O_3) = \frac{1}{2}B_2O_3 + 156·3$ Cals. Some idea of its affinity for some other elements may be gathered from the heats of formation with $\frac{1}{3}$B, with

	F	$\frac{1}{2}$O	Cl	Br	$\frac{1}{2}$S
Cals. . . .	78·3	45·4	31·1	14·4	13·8

J. H. Gladstone gave 4·0 for the **refraction equivalent** of boron, and 0·364 for the specific refraction. A. Schrauf has made observations on this subject. A. Ghira said that the at. refraction of combined boron is nearly independent of the elements with which it was united. As previously indicated, about the middle of the eighteenth century, J. H. Pott said that *le sel sédatif* communicates a green colour to the flame of alcohol, and that the colour is the same though a little feebler than that produced by cupric sulphate. The **spectrum** of the alcohol, Bunsen's or hydrogen flame coloured by boron compounds, was observed by J. F. W. Herschel, W. A. Miller, R. T. Simmler, R. Böttger, A. Mitscherlich, C. Horner, L. de Boisbaudran, W. Weith, J. M. Eder and E. Valenta, A. Hagenbach and H. Konen, A. de Gramont, M. W. Iles, L. Dieulafait, G. Salet, O. Vogel, etc. The flame spectrum of boric acid shows many bands, the most prominent of which are in the yellow and green ; they are essentially different from the similar coloured bands produced by barium compounds. The spectrum is shown in Fig. 2 ; there are three feeble orange-yellow bands, 6598, 6211, and 6032 ; a yellow band, 5808 ; an intense yellow band with sharp lines—5481 and 5440, α, Fig. 2—a feeble green band with lines 5193, β, Fig. 2, and 4912, γ, Fig. 2 ; and

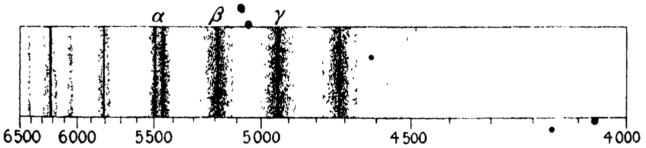

Fig. 2.—Spectrum of Boric Acid.

finally, a feeble blue band, 4722 and 4530. The flame spectrum is not easy to produce, it requires a large excess of boric acid, and the slit of the spectrum rather more open than usual. The three bands, α, β, and γ, with the green line 5481, and the weaker line 5440, are useful in the spectroscopic recognition of boric acid. The spectrum of boron fluoride is similar. The same bands are observed in the arc spectra of boron, boric oxide, and the spark spectrum of soln. of boric acid in hydrochloric acid; they are attributed to boron oxide; they do not occur in the spark spectrum of boron itself. According to W. Jevons, boron trichloride or methyl borate in the after-glow of nitrogen shows another series of bands which have definite heads and degrade towards the red; these bands also occur in the arc spectrum of boron and its oxide, and are attributed to boron nitride even though they do not occur in the spark spectrum of boron in nitrogen. The spectrum of boron fluoride in Geissler's tube was investigated by J. Plücker, G. Ciamician, etc. The band spectrum was studied by R. Thalén, L. Troost and P. Hautefeuille, C. P. Smyth, L. de Boisbaudran, G. Salet, F. Jones, A. Hagenbach, G. Kühne, H. Gilbert, H. Gilm, V. Merz and W. Weith, M. Bidaud, M. A. Catalan, H. Auerbach, etc. H. Rose showed that the presence of tartaric or phosphoric acid hinders the development of the green flame. The **spark spectrum** was investigated by W. N. Hartley, J. M. Eder and E. Valenta, F. Exner and E. Haschek, A. Hagenbach and H. Konen, etc. W. N. Hartley observed the three lines 3450·3, 2497·0, and 2496·3 when borax is volatilized in the electric arc. The spark spectrum obtained with electrodes of adamantine boron furnished J. M. Eder and E. Valenta 14 lines in the ultra-violet, namely, 3957·9, 3941·7, 3829·3, 3824·5, 3246·9, 2689·0, 2686·2, 2388·5, 2267·0, 2266·4, 2088·8, 2088·4, 2066·2, 2046·6, when the lines due to foreign metals are eliminated. The **arc spectrum** was studied by H. Kayser and C. Runge, H. A. Rowland and co-workers, F. Exner and E. Haschek, A. Hagenbach and H. Konen, etc. The effect of press. was studied by W. J. Humphreys. R. A. Millikan measured the extreme **ultra-violet spectrum** of boron. The wave-length of the *K*-radiation of boron has been measured by O. W. Richardson and C. B. Bazzoni, A. L. Hughes, and J. Holtsmark. The latter found $\lambda=83·6$. F. K. Richtmyer found a discontinuity in the **X-ray spectrum** of boron in the region of very short wave-lengths, and considered it as evidence of the presence of characteristic *J*-radiations. J. Holtsmark measured the characteristic X-rays of boron. J. C. McLennan and M. L. Clark gave 23·45 for the critical voltage of the *L*-series of X-rays from boron for $\lambda=525·8\times10^{-8}$ cms., and 42·2 volts for $\lambda=292·2\times10^{-8}$ cms. E. Rutherford and J. Chadwick obtained evidence of the emission of long-range particles, detected by scintillations on a zinc sulphide screen—probably hydrogen—when **α-rays** pass through boron.

J. L. Gay Lussac and L. J. Thénard said that the **electrical conductivity** of boron is nil. H. Moissan found that electrical conductivity of the pressed powder is very low, being but $0·125\times10^{-6}$ rec. ohms per cm. cube when that of mercury is $1·063\times10^{4}$ at 0°; and its **electrical resistance,** 807 megohms. A. H. Warth gave 9×10^{5} ohms per cm. calc. for the sp. resistance at 26°, and this falls considerably with rise of temp. E. Weintraub found fused boron, when cold, is a very poor conductor, for its sp. resistance is 10^{12} times that of copper at ordinary temp. In this respect, boron resembles carbon; but unlike carbon, boron has an abnormally high negative temp. coeff. of its resistance. Metals usually have a positive temp. coeff., and the metalloids a negative temp. coeff. The sp. conductivity of boron at 0° is nearly $0·5\times10^{-6}$ or $0·6\times10^{-6}$ mho per cm. cube, and it doubles in value for every 17°. The curve is shown in Fig. 3. The observed data are:

	0°	27°	100°	170°	320°	520°	600°
Ohms .	9×10^{6}	775×10^{3}	66×10^{3}	$7·7\times10^{3}$	180	7	4

Above 1000°, the resistance is but a fractional part of an ohm. The effect of traces of impurities in the boron is to raise the conductivity many-fold. Thus, one per cent. of carbon makes the remarkable character of the conductivity of boron disappear;

and its conductivity becomes comparable with that of carbon or silicon. With metals, the resistance, not the conductivity, increases if impurities are present. The negative temp. coeff. of impure boron becomes numerically less and less as the temp. increases; so that all the curves seem to converge at about 1000°. The behaviour of fused boron is more like that of a spark gap or arc than that of a solid conductor, for there exists a break-down voltage in the case of boron as in the case of an air-gap. Below the break-down voltage, only a very small current flows through a boron conductor, but once the current is started, boron becomes a relatively good conductor. Fig. 4, for example, shows the volt-ampere curve of boron in air. At 400 volts, the breakdown occurs when only 0·004 amp. is passing; after that the current rises, and the voltage drops rapidly. H. N. Warren used boron as the positive pole in a galvanic element. F. Zantedeschi said that boron is diamagnetic. K. Honda gave for the **magnetic susceptibility** at 18°, $-0{\cdot}71\times10^{6}$ mass units, and at 1100°, $-0{\cdot}80\times10^{6}$ units.

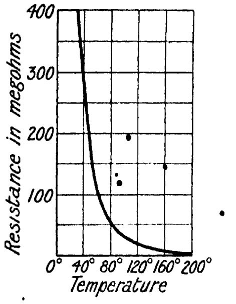

FIG. 3.—The Electrical Resistance of Boron.

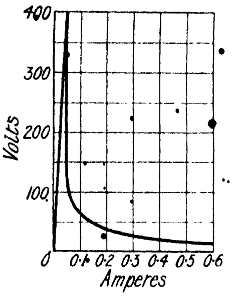

FIG. 4.—Volt-Ampère Curve of Boron in Air.

The fact that crystallized boron has not been prepared, and that the so-called graphitoidal and adamantine forms crystalline boron are not really boron, but rather compounds—aluminium borides, and aluminium borocarbides—or solid soln. does not render nugatory the published data respecting the properties of crystalline boron, but it renders it necessary to transpose the descriptions from the sections dealing with boron to those dealing with the corresponding compounds.

F. Wohler and H. St. C. Deville proved that *graphitoidal boron* is aluminium boride, AlB_2 (*q.v.*), and they also argued that the small proportion of carbon always associated with *adamantine boron* must be present as diamond-carbon because the crystals are transparent, and thus the larger the proportion of carbon the greater the transparency. As previously indicated, W. Hampe represented the composition by $Al_3B_{48}C_2$, and H. Biltz by $Al_3B_{44}C_2$, and, added the latter, it is not possible to say whether these crystals are a definite chemical compound—an *aluminium borocarbide*—or a saturated solid soln. The crystals are colourless or they vary in colour from a honey-yellow to a brownish-yellow, a hyacinth-red, a dark reddish-brown approaching black in transmitted light, and in reflected light they are dark brown to grey. L. Gattermann said that the crystals are six-sided plates; and F. Wöhler and H. St. C. Deville obtained eight-sided prisms with octahedral ends. A. Sella, and G. Sartorius agree that the crystals are bipyramids belonging to the tetragonal system, the axial ratios were given respectively as $a:c=1:0{\cdot}5762$ and $1:0{\cdot}5756$. F. Wöhler and H. St. C. Deville gave 2·68 for the sp. gr.; A. Wigand, 2·49; and H. Biltz, 2·590±0·006 at 18°/4°. F. Wöhler and H. St. C. Deville found the crystals to be so very hard that they readily scratch ruby and corundum, and even the diamond; and they stated that the crystals do not change when heated to the m.p. of iridium, and that in air they burn superficially at the same temp. as the diamond, forming a crust of boron oxide; H. V. Regnault found 0·250 for the sp. ht.; H. Kopp gave 0·230; A. Wigand, 0·165 at 21°; W. G. Mixter and E. S. Dana, 0·2518; and H. F Weber

	−39·6°	26·6°	27·6°	125·8°	233·2°
Sp. ht. . . .	0·1915	0·2382	0·2737	0·3060	0·3663

According to F. Wöhler and H. St. C. Deville, the crystals are doubly refracting. Adamantine boron is not attacked by acids, but aqua regia acts slowly; it is attacked by fused potassium hydrosulphate at red heat, forming sulphur dioxide; fused phosphoric acid forms boric oxide and a flame coloured by phosphorus; fused potassium nitrate has no action; fused sodium hydroxide or sodium carbonate forms a little sodium borate at a red heat, but a boiling aq. soln. of the former has no action. A. Ditte found that boric acid and iodine are formed when hydrogen iodide acts on adamantine boron at a red heat. M. Berthelot allowed chlorine to act on white-hot adamantine boron, and found that a part of the carbon is removed and deposited as graphite crystals a little distance away from the seat of the reaction; it was accordingly assumed that a compound with chlorine is formed and decomposed during the reaction.

The chemical properties of boron.—Most of our knowledge of the chemical properties of amorphous boron is a result of H. Moissan's [3] *Études sur le bore amorphe.* The samples here used were shown by E. Weintraub to contain 4–5 per cent. of oxygen. Summaries have been made by E. Davies, W. Müller-Erzbach, F. Tiemann, etc. According to H. Moissan, amorphous boron unites with the metalloids more readily than with the metals, and it has a strong affinity for oxygen, sulphur, fluorine, and chlorine. It is a more energetic reducing agent than carbon and silicon because it decomposes the oxides of these elements at a red heat. Its general chemical properties resemble those of carbon more closely than those of silicon. Indeed, boron resembles no other element so much as it does carbon. According to F. Wöhler and H. St. C. Deville, strongly calcined amorphous boron is less readily attacked by chemical agents than that which has not been calcined.

According to H. Davy, H V. Regnault, and F. Wöhler and H. St. C. Deville, boron is not influenced when heated to redness in **hydrogen,** and H. Moissan found the sp. gr. was not affected by heating boron to 1500° in hydrogen. H. B. Baker and H. B. Dixon found boron retains occluded hydrogen very tenaciously. J. L. Gay Lussac and L. J. Thénard said that amorphous boron does not oxidize in **air** at ordinary temp. B. Reinitzer found that very finely divided amorphous boron becomes covered with microscopic crystals of boric acid after 8–10 days' exposure to moist air. J. L. Gay Lussac and L. J Thénard state that the oxidation of boron in air begins at about 300°; it then burns in air with a reddish glow, and, added J. J. Berzelius, a green flame; scintillating parts are produced, some boric oxide sublimes, and a dark residue mixed with vitrefied boric oxide remains. H. Davy regarded the dark residue as *boron suboxide*, for he said that it contains less oxygen than is present in boric anhydride; J. J. Berzelius said that it is only boron changed physically by the high temp. of combustion; and it is probable that it contains a nitride. E. Weintraub showed that the brown amorphous boron prepared by the reduction of boric oxide or borax always contains oxygen, and he suggested that it is boron suboxide; more probably it is a solid soln. of boric oxide in boron. H. V. Regnault said amorphous boron oxidizes in air at 100°; F. Meyer and B. Zappner's product oxidizes on exposure to air; and F. Wöhler and H. St. C. Deville noted that the light flocculent boron burns in air when the temp. is slightly raised. H. Moissan said that the reports of the low temp. of the inflammation of boron are based on observations with samples contaminated with sodium boride; and he added that the purified product inflames in air when heated to 700°, and it burns with a brilliant green flame of low actinic power. The combustion is soon stopped by the formation of a layer of boric anhydride on the surface of the boron. E. Weintraub found that fused boron can be heated strongly in air without undergoing any perceptible oxidation. H. Moissan's boron behaves similarly in **oxygen** to what it does in air, but it ignites at a lower temp., and burns with a dazzling light. H. B. Baker and H. B. Dixon found the dryness of the oxygen has a marked influence on the results.

J. J. Berzelius said that the freshly prepared uncalcined amorphous boron is soluble in **water** to which it imparts a greenish-yellow colour, and that the boron s precipitated from its aq. soln. by acids and salts; the residue left on evaporating he liquid in a glass dish forms a yellowish film which is only partially taken up when treated with water. J. J. Berzelius was obviously dealing with a colloidal soln. G. Dragendorff thought that he had prepared hydrated boron by the reducing action of phosphorus on borax. J. L. Gay Lussac and L. J. Thénard said that amorphous boron does not decompose water at 100°; but F. Wöhler and H. St. C. Deville, and H. Moissan found that steam reacts with boron at a red heat, forming boric acid and hydrogen. Once the reaction is started it proceeds with great energy, forming boric acid and hydrogen. F. Ageno and E. Barzetti said that **hydrogen peroxide** is decomposed by a colloidal soln. of boron, and that boric acid is simultaneously formed.

According to H. Moissan, **fluorine** attacks boron at ordinary temp., the mass becomes incandescent, and boron trifluoride is formed. W. Muller-Erzbach studied the affinity of the halogens for boron. Boron takes fire in **chlorine** at 410°, forming boron chloride; H. Davy's impure boron ignited at ordinary temp. in chlorine. H. Moissan further observed that in **bromine** vapour, inflammation occurs at 700°, and boron bromide is formed. Bromine water attacks boron very slowly at ordinary temp., but the reaction is faster in the presence of potassium bromide. Boron is not attacked by **iodine** at ordinary temp., the reaction begins at about 1250°; iodine in the presence of water acts slowly on boron at ordinary temp. The hydrogen halides react with greater difficulty on boron; H. Moissan found that **hydrogen fluoride** is not attacked below dull redness; and F. Wöhler and H. St. C. Deville and H. Moissan found that **hydrogen chloride** attacks boron at a bright red heat—in both cases hydrogen and the boron halide are formed. The former added that if the reaction occurs in a glass tube, some silicon chloride is formed by the joint action of boron and hydrogen chloride on glass. Boron is not attacked by **hydrochloric acid,** sat. at 0°. H. Davy's impure boron was attacked by the boiling acid. H. Moissan found that **hydrogen iodide** does not attack boron at 1300°, but at a more elevated temp. boron iodide is formed. According to H. Moissan, boron reacts energetically with many metal fluorides, forming boron fluoride, the **fluorides of the alkalies and alkaline earths** are decomposed at a bright red heat; **zinc fluoride** is decomposed at a dull red heat; the reaction by simple contact with **lead and silver fluorides** proceeds with explosive violence. The reaction with the chlorides is not so energetic; the **chlorides of the alkalies, alkaline earths, zinc, and lead** are not attacked at a red heat, but **mercurous chloride** is reduced to mercury at 700°. F. Wöhler and H. St. C. Deville found that lead chloride, **mercuric chloride,** and **silver chloride** are reduced to the metal and boron chloride. H. Moissan found that boron reduces a soln. of **ferric chloride** to ferrous chloride, and soln. of **palladium and platinum chlorides** are reduced at ordinary temp.; J. J. Berzelius and H. Moissan stated that a soln. of **auric chloride** is reduced by boron to aurous chloride. The last named also found that boron does not reduce **lead, zinc, cadmium, and copper iodides** at a red heat, but **tin and bismuth iodides** are readily reduced. According to H. Moissan, **chloric acid** is reduced by boron to chlorous acid; and, according to A. Ditte and H. Moissan, **iodic acid** attacks boron below 40°, forming boric acid and iodine, at the same time, the mixture becomes incandescent; while the last named also found that iodine is precipitated from a cold aq. soln. of iodic acid. Fused **potassium chlorate** reacts vigorously with boron; each portion of boron which is projected on the fused mass produces *une lumière éblouissante.*

H. Davy's impure boron dissolved slightly in molten **sulphur.** According to H. Moissan, boron unites with sulphur in the vicinity of 600°, and the mass becomes incandescent—boron sulphide is formed; it behaves similarly with **selenium** at a more elevated temp., but it does not unite with melted **tellurium.** F. Wöhler and H. St. C. Deville found that boron sulphide is formed when boron is heated with **hydrogen sulphide.** At a dull red heat, boron reduces **sulphur dioxide** to sulphur. J. L. Gay Lussac and L. J. Thénard, and H. Davy said that boron readily decomposes hot conc. **sulphuric acid**; but is not attacked by the cold acid. H. Moissan found that the reaction begins at 250°, and sulphur dioxide is formed. F. Wöhler and H. St. C. Deville said that when boron is heated with **lead sulphide,** boron

sulphide and lead are produced. J. L. Gay Lussac and L. J. Thénard found that boron at a red heat reduces **sulphites** and **sulphates,** forming sulphur and the metal borate. The **sulphates of the alkalies and alkaline earths** were found by H. Moissan to be reduced to sulphides by boron at a red heat.

H. Moissan and G. Charpy found that **carbon** does not combine directly with boron, although a boron carbide is formed when boron is heated in the electric arc in an atm. of hydrogen. J. N. Pring and W. Fielding found that above 2000°, boron changes carbon catalytically into graphite. At 1200°, boron reduces **carbon monoxide** to carbon. According to R. Lorenz, **carbon dioxide** is likewise reduced by heated boron. H. Moissan heated boron to redness in the vapour of purified dried **carbon disulphide,** and obtained carbon and boron sulphide. According to P. C. Chabrié, **carbon tetrachloride** forms much boron chloride at 200°–250°: $4B+3CCl_4=3C+4BCl_3$; **chloroethene,** C_2Cl_4, acts less readily, and **hexachlorobenzene,** C_6Cl_6, not at all; **dibromoethane,** $C_2H_4Br_2$; and **tribromhydrin** likewise form much boron bromide in a sealed tube at 250°. J. L. Gay Lussac and L. J. Thénard found that when **carbonates** are heated with boron, carbon and the corresponding borate are formed. H. Moissan also found **sodium carbonate** is rapidly decomposed by boron at a dull red heat; **potassium carbonate** at a higher temp.; and **barium and calcium carbonates** not at all. H. Davy observed no reaction with **acetic acid.** He also found that **silicon** does not unite directly with boron; and that **silica** is reduced to silicon when the mixture is heated in a forge. A. Duboin and A. Gautier said that an intimate mixture of boron and silicon behaves like carbon in the presence of alumina. According to L. Troost and P. Hautefeuille, when boron is heated with silicon dioxide, silicon and boric oxide are formed. Similar results were obtained with **zirconium dioxide,** and **titanium dioxide.**

F. Wöhler and H. St. C. Deville, and H. Moissan stated that boron unites with **nitrogen** at 1230°. The last named found that boron is without action on **nitrogen peroxide.** F. Wöhler and H. St. C. Deville found that amorphous boron burns when heated in an atm. of **nitric oxide,** forming boron nitride and boric oxide. F. Wöhler said the action starts at a red heat. H. Davy noted that boron burns in **nitrous oxide,** forming boric oxide—H. St. C. Deville and F. Wöhler showed that some boron nitride is produced as well. The last named also found that when boron is heated in a stream of **ammonia,** boron nitride is formed. J. L. Gay Lussac and L. J. Thénard stated that feebly warmed **nitric acid** is decomposed by boron, furnishing boric acid, nitric oxide, and nitrogen; they also stated that **nitrates** and **nitrites** are vigorously decomposed by boron. H. Moissan also found nitric acid reacts energetically with boron, and that with the conc. acid the reaction is so vigorous as to raise the mass to incandescence; F. Meyer and R. Zappner's boron is a fine powder which reacts violently with dil. nitric acid, and inflames on contact with the conc. acid. On the contrary, E. Weintraub's fused boron is scarcely attacked when gently warmed with 10 per cent. nitric acid, under conditions where amorphous boron is readily attacked. Notwithstanding its great affinity for oxygen, boron may be immersed in fused **potassium nitrate** up to about 400°, without any reaction taking place, but as soon as the potassium nitrate begins to decompose an energetic reaction occurs; a mixture of boron, sulphur, and nitre deflagrates at a dull red heat. Molten **potassium nitrite** is violently decomposed by boron. H. Moissan found that a soln. of **silver nitrite** is reduced by boron, forming crystalline silver. H. Davy's impure boron was slightly attacked by molten **phosphorus,** but H. Moissan found that boron does not unite directly with phosphorus, **arsenic,** or **antimony** at 750°; **phosphorus pentoxide** at 800° is reduced to phosphorus; **arsenious acid** and **arsenic acid** are reduced to arsenic at 800°; and the **arsenites** and **arsenates** are reduced at a dull red heat; **antimonious oxide** is also readily reduced when heated with boron. The **chromates** are likewise reduced at dull redness, and a cold soln. of **potassium permanganate** is decolorized by boron.

According to H. Moissan, the **alkali metals** have no action on boron, and they can be distilled from boron without combination; **magnesium,** on the contrary, gives a boride at a dull red heat; **iron** and **aluminium** form borides only at a high temp.; while **silver** and **platinum** readily combine with boron. H. Moissan and G. Charpy found that when reduced iron is melted with boron in an atm. of hydrogen, about 10 per cent. of the latter is dissolved. The **ferroboron** so produced can be alloyed with steel, and the tensile strength of the steel is increased without perceptibly affecting the hardness. H. Davy observed no reaction when boron is heated with **mercury**, and A. B. du Jassonneix that at the temp. of an electric furnace, boron is insoluble in **copper, tin,** and silver. E. Weintraub also found boron does not alloy with copper at a red heat, and P. C. Ray observed a similar result with **magnesium.**

H. Davy's impure boron was attacked by fused and aq. soln. of the fixed alkalies. According to J. J. Berzelius, when boron is heated with **potassium hydroxide,** potassium borate and hydrogen are formed; H. Moissan observed a similar action with the molten hydroxide, and he found that the metallic oxides are reduced more readily by boron than by carbon. For example, when a mixture of **cupric oxide** and boron is warmed in a glass tube, the action is violent and the glass is melted; **stannous oxide, lead oxide,** and **bismuth oxide** are readily reduced; a mixture of boron and **lead dioxide** detonates violently when triturated in a mortar. At a red heat, the **alkaline earth oxides** are not affected; but **ferric and cobalt oxides** are reduced. H. Giebelhausen found that amorphous boron dissolves in **calcium fluoride** and the boron crystallizes out on cooling; with **cadmium fluoride,** boron fluoride and cadmium are formed.

The volatility of boron prevents its use in making filaments for electric lamps. E. Weintraub recommends it strongly for purifying copper; he said that if 0·03–0·1 per cent. be added to molten copper before it is cast, the metal is deoxidized and purified to a remarkable extent. He added that it is cheaper to use the amorphous powder than fused boron. The product was called *boronized copper,* although it is virtually free from boron. The term, therefore, refers to a mode of treatment rather than to its chemical composition. Similar remarks apply to the *bronze silicieux* which F. Gautier found to contain no silicon. According to L. Guillet, H. Moissan and G. Charpy, and G. Hannesen, a little boron increases the breaking stress of steel.

Reactions of analytical interest.—When a moderately conc. soln. of borax is treated with one of **silver nitrate,** a white precipitate of metaborate, $AgBO_2$, is formed, soluble in ammonia or nitric acid; when the silver metaborate is warmed, brown silver oxide is formed; with cold dil. soln., silver oxide is precipitated. Fairly conc. soln. of borax with **barium chloride** give a white precipitate of barium metaborate, $Ba(BO_2)_2$, soluble in an excess of barium chloride, and in soln. of ammonium salts and acids. A soln. of **calcium chloride** or of **lead chloride** behaves like that of barium chloride; and a soln. of **mercuric chloride** gives a red precipitate. The latter reaction is sometimes styled G. Tammann's reaction[4] for free borates.

A hot very conc. soln. of an alkali borate may give a precipitate of boric acid when treated with **hydrochloric acid**; again, **sulphuric acid** exerts no visible action on a soln. of borax, but most borates are decomposed by this acid liberating boric acid. A soln. of boric acid dissolves in **alcohol,** and the alcohol burns with a green flame—*flame test.* Similarly, if a borate be decomposed by an acid, and the mass be mixed with alcohol, the latter burns with a green flame. The test is conveniently made on a watch glass. Methyl alcohol gives better results than ethyl alcohol. It is possible to detect 0·001 per cent. of boric oxide in a soln. by this test. If copper or barium be present the test is not satisfactory—the former must then be removed by hydrogen sulphide, and the latter by sulphuric acid. According to M. W. Iles,[5] the test is best conducted by heating the borate moistened with sulphuric acid on a platinum foil until all the acid is expelled. It is then moistened with glycerol, and the latter ignited. A flame tinged green is produced if boric oxide be present; and 0·001 per cent. of boric acid can be detected by this reaction. According to E. Turner, if a powdered borate be mixed with a few drops of water, and approximately three times its weight of Turner's flux—a mixture of powdered calcium or potassium fluoride with 4–5 times its weight of potassium hydrosulphate —and the paste exposed on a loop of platinum wire in the blowpipe (or Bunsen's) flame, boron fluoride is volatilized and it imparts a greenish tinge to the flame. The reaction will detect 0·01 grm. of boric acid in a silicate.

If a borate be just acidified with dil. hydrochloric acid, and a strip of turmeric paper be half immersed in the soln., no apparent change occurs ; but if the paper be dried on a watch-glass at 100°, the half which has been dipped in the boric acid shows a peculiar brownish-red coloration—**turmeric** test. If but a small trace of boric oxide be present, the stain may be pink. The colour remains when the stain is dipped in boric acid again, or in dil. sulphuric or hydrochloric acid. The brown stain produced by alkalies changes into yellow under these conditions. If too little acid be used, there may be no coloration ; if too much, the colour may be brown. If the boric acid stain be touched with a soln. of potassium hydroxide, the paper becomes bluish-black or bluish-grey, according as much or little boric acid be present. A little hydrochloric acid will restore the red colour. As little as 0·0001 grm. of boric acid can be detected by the (pink) colour produced in this manner. The presence of oxidizing agents like chlorates, chromates, iodides, etc., interferes with the test by destroying the turmeric. Nitric acid is an exception. Conc. hydrochloric acid may give a dark brown stain under the conditions of the test ; ferric chloride, molybdenum, and zirconium salts give a brownish-red stain which is not coloured bluish-black with potash soln.

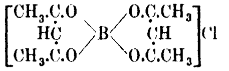
Still smaller amounts of boric acid can be detected if needed by placing the soln. under investigation in a small dish and evaporating it to dryness in a desiccator in vacuo at a low temp. If a few drops of an alcoholic extract of a few turmeric papers be mixed in a porcelain dish with the borate, the soln. acidified with acetic acid, and evaporated to dryness on a water-bath, a reddish-brown residue will be obtained if as little as 0·0002 grm. of B_2O_3 be present, while 0·00002 grm. will produce a perceptible coloration.

Boric acid reacts feebly acid towards **litmus** ; and the alkali salts react alkaline ; the colour of **methyl orange** or of **p-nitrophenol** is not affected by boric acid ; a soln. of boric acid neutralized with alkali hydroxide, with **phenolphthaleïn** as indicator, again gives an acid reaction if glycerol or mannite be added to the soln. If an aq. soln. of boric acid be titrated with a standard soln. of sodium hydroxide, the pink colour of phenolphthaleïn is developed before all the boric acid is neutralized ; but if the soln. contains sufficient glycerol or mannitol, the boric acid all reacts with the sodium hydroxide : $NaOH+H_3BO_3=2H_2O+NaBO_2$, before the pink coloration appears. A volumetric process is based on this reaction. If a standard soln. of hydrochloric acid be added to a soln. of borax with methyl orange or better, *p*-nitrophenol, as indicator, the soln. reacts acid only when all the sodium is neutralized by hydrochloric acid : $Na_2B_4O_7+5H_2O+2HCl=2NaCl+4H_3BO_3$. The liberated boric acid can then be titrated with standard alkali with phenolphthaleïn as indicator.

If a borate be distilled with sulphuric acid and methyl alcohol, a volatile methyl borate, boiling at 65°, distils over ; with ethyl alcohol a volatile ethyl borate, boiling at 120°, is obtained. The alkyl borate can be saponified with alkali hydroxide, and the boric acid determined by volumetric methods, *vide supra*, or weighed as potassium fluoborate.

Determination of the atomic weight of boron.—The accurate determination of the at. wt. of boron has presented many difficulties because of the small number of compounds which are suited to accurate measurements. J. L. Gay Lussac and L. J. Thénard[6] said that when oxidized with nitric acid boron takes up about one-third of its weight of oxygen ; this would make the at. wt. 48—oxygen, 16 ; H. Davy found that when one part of boron is burnt in oxygen, it takes up 1·8 parts of oxygen. This would make the at. wt. 13·3. The samples of boron employed were very impure. T. Thomson discussed the at. wt. of boron in 1824. In J. J. Berzelius's list of 1815, a number corresponding with 11·15; if oxygen be 16, was given; and in 1818, he gave 11·15. At first, J. J. Berzelius wrote the formula of boron oxide, B_2O_3, and he later changed this to BO_2 (with oxygen=8), thus making the at. wt. of boron approximately 22—some wrote the formula BO_2. V. Kletzinsky in 1865 wrote the formula BO_6 (with oxygen 8), and gave 44 for the at. wt. The at. wt. of boron=11, is in harmony with values deduced by Avogadro's rule from the volatile compounds of boron.

In its compounds with the electronegative elements boron is tervalent, and highest known oxide is the trioxide $(B_2O_3)n$; no halide is known higher than BF_3 or BCl_3; and in the boron alkyls, $B(CH_3)_3$ and $B(C_2H_5)_3$, boron is undoubtedly tervalent. It has been argued that if three represents the maximum valency of boron, the boron alkyls and halides would probably be chemically inert like the hydrocarbons, and carbon tetrachloride; on the contrary, the boron halides and alkyls are very reactive, and readily unite additively with ammonia, potassium hydroxide, etc., forming compounds like $B(CH_3)_3.NH_3$, $B(CH_3)_3.KOH$, HBF_4, $BCl_3.NOCl$, $BCl_3.HCy$, $BCl_3.C_2H_5Cy$, $BCl_3.CyCl$, etc., in which it is supposed the boron is quinquevalent. It is also said to behave as a quinquevalent element in ammonio-boron trimethyl, and in the *boronium* compounds of J. Schumacher *e.g.* acetylacetoneboronium chloride, which he represents by the formula



$H_3N:B(CH_3)_3$ and in boric ethopentaethylate, $(C_2H_5O)_3B:B(C_2H_5)(OC_2H_5)_2$, as shown by E. Frankland in 1876; in monophenyl boron chloride, $C_6H_5BCl_4$, as shown by A. Michaelis and P. Becker; in the pyrocatecholboric acid, $(C_6H_4O_2)_2''BH$, of J. Boeseken, and P. H. Hermans; in sodium ethyl borate, $Na.B(OC_2H_5)_4$, or $NaO.B(OC_2H_5)_3.C_2H_5$, in boron pentasulphide, B_2S_5, prepared by H. Moissan; in M. Travers and P. C. Ray's borohydrates; and in boron oxytrichloride, $BOCl_3$, reported by C. Councler, but shown by R. Lorenz to be more probably $B_8O_{11}Cl_2$. The existence of neither $BOCl_3$ nor of B_2S_5 has been confirmed. J. Boeseken regarded the existence of the quinquevalent boron compounds as lending support to the octet theory of valency; and to be explained on the same lines as that of the ammonium compounds, but whereas the nitrogen atom has to lose an electron in order to become quinquevalent, thereby becoming an electropositive ion, the boron atom has to gain an electron, forming an electronegative ion. In boron fluoride, BF_3, the outer electron shell of the boron atom contains six electrons, shared in pairs with the fluorine atom. When combining with another mol. of hydrogen fluoride, the boron atom completes its octet by sharing with the new fluorine atom one of the electrons of the latter and a hydrogen electron. By taking the hydrogen electron, however, it forms the negative ion, BF_4', and the positive ion, $H^{\cdot}$. It follows that when boron is functioning as a quinquevalent atom four of its valencies are non-polar and the fifth polar, as in the case of nitrogen. Boron functions as a quadrivalent element when a normal boron compound such as BF_3 combines with a mol. containing two available electrons in the outer shell of one of its atoms, for instance, ammonia. Thus the stable compound, BF_3, NH_3, can be formulated as in Fig. 5, in which the boron atom appears truly quadrivalent, as does the nitrogen. A. Stock and co-workers stated that the evidence for the quinquevalency of boron is feeble and indecisive, and that the maximum valency of boron is four. He added that G. Bodländer and R. Abegg's rule that the sum of the maximum positive and negative valencies of all elements is 8, does not apply in the case of boron.

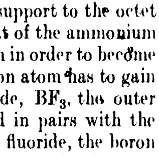


FIG. 5.—Electronic Structure of $BF_3.NH_3$.

The at. wt. 11 is almost in harmony with the position of boron at the head of the third group of the periodic table assigned to it by D. I. Mendeléeff. P. Georgievic argued that the right position of boron in the periodic table is in the aluminium group because (i) its oxide acts like aluminium oxide as a feeble base and as a feeble acid; (ii) the alkyl compounds of the two elements are similar; and (iii) the isomorphism of euclase and datolite. A. Étard placed it at the head of the vanadium group very near to phosphorus: N, P, As, Sb, Bi, . . . B, V, Nb, Ta, . . . The abnormal sp. ht. of boron made the at. wt. 11 not fit well with Dulong and Petit's rule. N. Delaunay made some observations on the at. wt. of boron with other elements.

Preliminary experiments were made by J. J. Berzelius with boric acid; and by A. Arfvedson with borax. These are so discordant with later values that they are usually omitted from calculations. Some years later, in 1822, J. J. Berzelius made determination based on three concordant measurements of the per cent. of water in borax, and from the ratio, $Na_2B_4O_7.10H_2O : 10H_2O$, he calculated 11·08; from the same ratio, A. Laurent (1849) calculated 11·85; V. Dobrovolsky (1896), 10·87; J. L. H. Abrahall (1892), 10·70; W. Ramsay and E. Aston (1893), 10·94; and F. P. Armitage (1898), 10·99. There are special sources of error connected with the use of borax due to (i) the difficulty in ensuring complete dehydration by ignition, but, said V. Dobrovolsky, this readily can be ensured if small quantities are employed; (ii) the possibility of volatilizating both soda and boric acid during the ignition as shown by N. Leonard; (iii) the difficulty in avoiding the inclusion of some mother liquid during the crystallization of borax; and (iv) the difficulty in accurately weighing the crystals owing to efflorescence if the vap. press. of the hydrated salt is greater than that of the humidity in the atm., and to the surface condensation moisture when the humidity of the atm. is greater than the vap. press. of the crystals. R. Fresenius also wrote on this subject. The risks are illustrated by J. L. H. Abrahall who found that crystallized borax contained 47·286 per cent. of moisture, and W. Ramsay and E. Aston, 47·168 per cent.

In 1824, J. J. Berzelius transformed borax into sodium sulphate by igniting it with sulphuric and hydrofluoric acids, and, from the ratio $Na_2B_4O_7.10H_2O : Na_2SO_4$ he calculated the at. wt. 11·0. W. Ramsay and E. Aston distilled dehydrated borax with hydrochloric acid and methyl alcohol, and from the ratios $Na_2B_4O_7 : 2NaCl$ calculated the at. wt. 10·96 and 10·97. They also converted the sodium chloride into silver chloride, and from the ratios $Na_2B_4O_7 : 2NaCl : 2AgCl$ calculated the at. wt. 11·05. E. Rimbach titrated a soln. of borax with hydrochloric acid with methyl orange as indicator, and from the ratio $NaB_4O_7.10H_2O : 2HCl$ calculated the at. wt. 11·01; F. P. Armitage titrated a soln. of fused borax with sulphuric acid, and from the ratio $Na_2B_4O_7 : H_2SO_4$ obtained the at. wt. 10·94. G. P. Baxter and A. F. Scott determined the ratios $BCl_3 : 3Ag$ and $BBr_3 : 3Ag$, and obtained 10·83 ± 0·01 for the at. wt. of boron; O. Hönigschmid and L. Birckenbach obtained from the ratios $BCl_3 : 3Ag$, and $BCl_3 : 3AgCl$, 10·82.

In 1859, J. B. A. Dumas communicated the results of experiments by F. Wöhler and H. St. C. Deville on the composition of the boron halides in which the ratio $BCl_3 : 3AgCl$ give numbers corresponding with 10·62 to 11·06, and the ratio BBr3 : 3AgBr, 10·96 for the at. wt. of boron; for the latter ratio, H. Gautier (1890) obtained 11·02 and 11·03, and for the ratio $BCl_3 : 3AgCl$, 10·95. J. L. H. Abrahall obtained for the ratio $BBr_3 : 3Ag$, 10·82 and 10·90. It is very difficult to prepare the boron halides quite free from hydrogen halides. H. Gautier converted boron sulphide into the sulphate, and from the ratio $B_2S_3 : 3BaSO_4$ obtained the at. wt. 11·04; H. Gautier also burnt boron carbide, and from the ratio $B_6C : CO_2$ calculated the at. wt. 11·00. A. Stock and E. Kuss measured the hydrogen evolved in the reaction $B_2H_6+6H_2O=2H_3BO_3+6H_2$, and from the results calculated for the at. wt. of boron 10·8055 (H=1·0077). F. H. Loring calculated 10·77.

In 1898, T. W. Richards gave 10·95 as the best representative value for the at. wt. of boron; and in 1910, F. W. Clarke calculated the general mean to be 10·9805 ± 0·0013, but added: "the uncertainties are so great that the final mean may be allowed to stand until better evidence as to the true at. wt. of boron is obtained." B. Brauner also wrote in 1905: "We know little more about the at.

wt. of boron than was known in 1824, that is that the at. wt. is 11·0; but we cannot say with any assurance whether the true at. wt. is greater or less than this value." The International Committee on Atomic Weights gave 11·0 for the best representative value of this constant.

The **atomic number** of boron is 5. F. W. Aston[7] found that boron has two **isotopes** of at. wt. respectively 10 and 11, and that the evidence is against the presence of a third isotope. F. H. Loring has discussed this subject. H. V. A. Briscoe and P. L. Robinson, in some preliminary observations on the ratio $BCl_3 : 3Ag$, found for Tuscany and Asia Minor minerals the at. wt. 10·82, and for a United States mineral, 10·84 ($Ag = 107{\cdot}880$, $Cl = 35{\cdot}460$). E. Rutherford and J. Chadwick, and G. Kirsch and H. Pettersson found that long-range particles were liberated from boron when bombarded by α-rays. These were assumed to be hydrogen nuclei, resulting from the **decomposition of boron atoms**. The distribution of momentum in terms of the initial velocity of the α-particles has been measured, and it is estimated that there is a 42 per cent. gain in energy as a result of the assumed disintegration of the boron. N. V. Sidgwick discussed the **electronic structure** of the atoms.

§ 4. The Borides

H. Davy[1] stated that potassium united with boron to form a grey mass of **potassium boride** which was decomposed by water into potassium hydroxide, and boron hydride; but J. L. Gay Lussac and L. J. Thénard said that only a mixture is formed in this way. H. Moissan found that the alkali metals can be distilled from boron without reaction, but by reducing boric oxide with metallic sodium he found a little **sodium boride** is formed.

H. Giebelhausen[2] said that amorphous boron is not dissolved and is hardly wetted by molten copper. H. N. Warren electrolyzed a molten borate with a molten copper cathode, and obtained what he regarded as a copper boride; E. H. and A. H. Cowles used a mixture of boric acid and copper as an electrically heated resistance, and they found a little boron raised the tenacity of copper without affecting its resistance. R. S. Marsden claimed to have prepared a **copper boride,** Cu_3B_2, by heating for 3–4 hrs., to a temp. above the m.p. of copper, a mixture of the two elements in a porcelain crucible placed in a graphite crucible and packed with carbon. The reddish-yellow metallic mass was cleaned from the boron nitride. The product had the colour of iron pyrites; it is hard enough to scratch bronze but not steel or glass; it is malleable but brittle; and its sp. gr. is 8·116, that of copper being 8·921. Analysis agreed with Cu_3C_2, or Cu : B.Cu.B : Cu. K. Nischk described the preparation of alloys of copper and boron; on the contrary, A. B. du Jassonneix found that boron is insoluble in copper at the temp. of the electric furnace; S. A. Tucker and H. R. Moody also failed to make a copper boride, and they added, "there does not seem to be any affinity between boron and the members of the copper group."

H. Giebelhausen said that amorphous boron is not dissolved, and hardly wetted by molten silver. Similar results were obtained by A. B. du Jassonneix with silver and boron as he obtained with copper and boron. Boron was found by H. Moissan[3] to precipitate metallic silver from a soln. of silver nitrate ; and the brown precipitate obtained by P. Sabatier by passing gaseous boron hydride into a soln. of silver nitrate was found by C. Winkler to be metallic silver. H. N. Warren claimed to have made an alloy of silver with 3 per cent. of boron as **silver boride** by heating potassium borofluoride with sodium and silver in a blast flame ; and a 6 per cent. alloy by heating a mixture of boron oxide, silver, and magnesium in an iron crucible lined with carbon. The yellow regulus dissolved with difficulty in nitric acid, and was little attacked by hydrogen sulphide.

According to H. C. Geelmuyden, when a mixture of boric oxide and calcium carbide is heated for 5 mins. in an electric furnace, **calcium boride,** CaB_6, is formed. E. Wedekind obtained a theoretical yield by heating in an iron tube under press. a mixture of 30 grms. of calcium metaborate with 50 grms. of calcium, and extracting the product first with dil. acetic acid, then with dil. hydrochloric acid, and finally with hot water. Barium borate and calcium treated in a similar manner gave a product which always contained some calcium. W. Muthmann and L. Weiss made calcium boride by heating a mixture of calcium and calcium borate at 1400°. E. Jüngst and R. Mewes made calcium boride and **barium boride,** BaB_6, by heating the chloride or fluoride with an excess of boron in the electric furnace, and H. Moissan and P. Williams made both these borides as *well as* ***strontium boride,*** *SrB_6, by heating an intimate mixture of the alkaline* earth borate, say, borate (1000 grms.), sugar charcoal (200 grms.), and aluminium (630 grms.) in a carbon crucible in an electric furnace for 7 mins. The powdered crystalline product was washed with dil. hydrochloric acid, and the residue boiled with the conc. acid, washed with water, and then with ether and toluene. The product was treated in turn with hydrofluoric acid, water, and ether until the latter was no longer coloured. The resulting boride was contaminated with a little graphite and boron carbide. A. Stock and W. Holle found the product of the action of calcium on boric oxide is calcium boride, not boron as supposed by H. Moissan. All three borides are black crystalline powders consisting of rectangular or cubic crystals which are transparent in thin layers and have a yellowish- or reddish-brown colour. H. Moissan gave for the sp. gr. of calcium boride, 2·33, strontium boride 3·28, and barium boride 4·36, all at 15° ; E. Wedekind gave 2·11 at 18° for the sp. gr. of calcium boride. The crystals scratch the ruby but not the diamond. The borides all melt in the electric furnace. E. Wedekind found that calcium boride is a conductor of electricity, and if an arc be struck between two electrodes made by compressing powdered calcium boride, the masses sinter leaving a product which cuts glass. When heated in air, calcium boride is superficially oxidized. H. Moissan found that hydrogen has no action on the boride at a red heat ; fluorine reacts in the cold with incandescence ; chlorine reacts at a red heat, forming chlorides of the constituent elements ; bromine and iodine act more slowly ; bromine water, or a mixture of potassium chlorate and hydrochloric acid, acts slowly ; the red-hot boride burns when heated to redness ; water at ordinary temp. has no action nor does it act under press. at 250°, but above this temp. a skin of boric acid and calcium hydroxide is formed ; the hydrogen halides attack the boride slowly at a red heat ; the corresponding acids have no action ; sulphur acts at a bright red heat ; dil. sulphuric acid has no action, while the conc. acid furnishes sulphur dioxide ; nitrogen at 1000° has no action ; ammonia does not act at the softening temp. of glass ; dil. and conc. nitric acid act vigorously ; oxidizing agents like lead oxide or potassium nitrate act energetically at a red heat ; and similar remarks apply to potassium carbonate, hydroxide, and hydrosulphate.

P. Lebeau[4] claimed to have made a crystalline mass of **beryllium boride** or possibly *beryllium borocarbide*, $Be_3B_3C_2$, of sp. gr. 2·4, by melting beryllia with boron in a carbon crucible. The product was not attacked by hydrofluoric, hydrochloric, sulphuric, or nitric acid ; it was not attacked by oxygen at 20°, but there was a slight action at 800° ; and chlorine attacked it with incandescence at 450°. T. L. Phipson,[5] and H. Moissan claimed to have made a mass containing magnesium boride by reducing boric oxide with magnesium; the dark green mass was decomposed by water. A. Geuther made **magnesium boride,** Mg_3B_2, by heating sodium fluoborate with magnesium; E. Jüngst and R. Mewes heated magnesium chloride in an electric furnace with an excess of boron and obtained a grey mass of the boride; F. Jones and R. L. Taylor represented the reaction between magnesium and boric oxide by $6Mg+B_2O_3=Mg_3B_2+3MgO$, and the reaction between boric chloride and magnesium by $6Mg+2BCl_3=Mg_3B_2+3MgCl_2$. The product obtained by the last-named process is black and deliquescent owing to its being contaminated with some magnesium chloride. This product has much impurity; when treated with conc. hydrochloric acid, spontaneously inflammable gas is obtained, presumably derived from the presence of magnesium silicide as an impurity. A. Stock and C. Massenez made magnesium boride by heating to redness an intimate mixture of powdered boron trioxide with three times its weight of magnesium powder in a thin-walled iron crucible. The yield is reduced if the temp. is too high; if a clay or porcelain crucible be used, the product is contaminated with silicon; and a nickel crucible is more attacked by the fused mass than an iron crucible. The fusion is best conducted in an atm. free from oxygen and nitrogen. The boride is but slowly attacked by water with the formation of traces of boron hydride; it is slowly attacked by acetic acid, and rapidly attacked by a sulphuric or hydrochloric acid, forming a mixture of boron hydride gases contaminated with traces of carbon dioxide and silicon hydride; a brown residue remains undissolved, and the soln. contains derivatives of the lower boron oxides. M. W. Travers and P. C. Ray showed that probably *magnesium diboride*, MgB_2, or Mg_2B_4, also exists.

H. St. C. Deville[6] made an alloy of aluminium with boron by melting the metal with borax, boric acid, or potassium fluoborate. H. N. Warren also introduced aluminium into a fused mixture of fluorspar and boric acid. In both cases the white alloy was brittle. T. S. Hunt made aluminium boride by the electrolysis of boron with fused alumina and powdered carbon. F. Wöhler and H. St. C. Deville showed that the so-called *graphitförmige Bors* is really **aluminium diboride,** AlB_2, or Al_2B_4, and they made it by heating a mixture of boron and aluminium, or of boric oxide and aluminium for a short time at not too high a temp.; by passing boron chloride over heated aluminium; or by melting a mixture of potassium fluoborate (8 parts), potassium and sodium chlorides (16 parts), and aluminium (5 parts) at the m.p. of silver. The excess of aluminium was removed by treatment with hydrochloric acid; sodium hydroxide; and hydrofluoric acid. F. E. Weston and H. R. Ellis reduced boron trioxide with aluminium powder by the thermite reaction, and boiled the product with hydrochloric or hydrofluoric acid, or fused it with borax and extracted it with water. A residue containing aluminium boride and alumina remained. F. Wöhler and H. St. C. Deville said the crystals of aluminium boride were six-sided plates, and W. Sartorius von Waltershausen made some observations on them. The former regarded them as identical with the monoclinic crystals measured by W. H. Miller, but it is not clear what crystals the latter really did measure. W. Hampe said that the crystals of the diboride appear as copper-red plates, and he showed that the crystalline boron prepared by F. Wöhler and H. St. C. Deville is really a mixture of **aluminium dodecaboride,** AlB_{12}, or Al_2B_{24}, and aluminium borocarbide—*q.v.* W. Hampe made it by fusing aluminium with boric oxide; by fusing aluminium with boric oxide and cryolite or fluorspar; and by passing boron fluoride over heated aluminium. The first process gave the best results, the most important condition for the success being the absence of carbon; the temp. of melting iron maintained for 2 to 3 hrs. was sufficient to produce the crystals, but the yield was larger at higher temp. According to H. Biltz, the black crystals, being specifically lighter, can be separated from those of aluminium borocarbide by flotation in a mixture of methylene iodide and benzene. A. Joly also prepared crystals of the dodecaboride, and H. Biltz made it by heating a mixture of boric oxide (250 grms.), sulphur (250 grms.), and aluminium (600 grms.). The cold product was decomposed by water, the resulting aluminium hydroxide removed by levigation, and the globules of aluminium picked out. The mass was digested successively with conc. hydrofluoric acid, hydrofluoric acid and dil. hydrochloric acid, for many days. W. Hampe stated that the crystals are black or in very thin laminæ dark red, and yield a brownish-red powder; they belong to the monoclinic system; H. Biltz gave $a:b:c=0·7130:1:0·7139$ for the axial ratios; W. Hampe said that the sp. gr. at 17·2° is 2·5345; H. Biltz found 2·455±0·005 at 18°/4°. The hardness is greater than that of corundum, and smaller than that of the diamond. According to W. Hampe, the crystals become steel-blue when heated in air, and do not change when heated in oxygen at the temp. at which the diamond easily burns; they are not attacked by hydrochloric acid; scarcely attacked by an aq. soln. of potassium hydroxide; scarcely attacked by boiling conc. sulphuric acid; gradually dissolved completely by hot conc. nitric acid—with the production of some aluminium hydroxide; oxidized with incandescence by molten potassium hydroxide, or lead chromate; not attacked by molten potassium nitrate; and slowly dissolved by molten potassium pyrosulphate. This boride forms a fusible alloy with platinum. H. Giebelhausen found that amorphous boron is not dissolved, and hardly wetted by molten thallium and no *thallium boride* has been made.

H. Moissan [7] noticed that when boron is vaporized in the electric arc, the tips of the electrodes have black masses formed by the union of carbon and boron to form **boron carbide** or **carbon boride,** and he stated that when the two elements are heated in the electric furnace, two borides are formed—one **carbon hexaboride,** CB_6, is stable, and the other product is alone attacked by a mixture of potassium chlorate and nitric acid. The hexaboride was found by A. Joly among the products obtained in the preparation of adamantine boron—*q.v.* H. Moissan gave three methods of preparation: (i) by passing an arc between carbon electrodes which are bound together with a mixture of boric oxide and aluminium silicate—the product was found to be contaminated with silicon carbide; (ii) by heating amorphous boron with carbon to about 3000°, either by placing the mixture directly in the arc, or by exposing it to the radiant heat of the arc in a small covered carbon crucible; and (iii) by dissolving boron and carbon in certain metals—silver or copper—in the electric furnace, and dissolving out the metal with nitric acid. H. Gautier also employed the last-named process, which is considered to be the most suitable for the purpose. S. A. Tucker and H. J. W. Bliss introduced powdered boric oxide into an arc-furnace in which a layer of petroleum coke at the bottom of a carbon crucible formed one pole, and the other pole consisted of a graphite rod hung vertically. J. N. Pring and W. Fielding fitted a strip of carbon in water-cooled brass tubes filled with graphite and pieces coppered and soldered to the brass tubes. This arrangement was fitted in a large glass globe through which a mixture of boron chloride and hydrogen was allowed to circulate, when the carbon strip was at 1500°, a deposit of free boron was formed; at 1750°, boron carbide commenced to form; at 2150°, large crystalline masses of the carbide were formed; and at 2200°, the boron carbide was dispersed (not volatilized) and deposited on the water-cooled brass tubes. According to E. Podszus, at about 2000° boron nitride is converted by carbon, carbon monoxide, or hydrogen and carbon disulphide into boron carbide. J. M. Logan made the carbide by heating mixtures of boric oxide and carbon in an electric furnace; and C. E. Parsons, a mixture of borax and carbon. K. Nischk studied the formation of carbon boride, and the affinity of carbon for boron.

Carbon hexaboride is a black crystalline substance with a metallic lustre. H. Moissan gave 2·51 for the sp. gr., S. A. Tucker gave 2·7, and A. Joly, 2·542 at 17°. S. A. Tucker said that the compound is harder than silicon carbide, and H. Moissan also noted its extreme hardness. Hence, it was recommended by H. Moissan for cutting diamonds; and by S. A. Tucker for drills in rock boring; for cutting rocks and glass; grinding wheels; in wire-drawing, etc. J. N. Pring and W. Fielding gave 2350° for the m.p., and added that it does not undergo any appreciable decomposition or volatilization below 2800°. W. R. Mott said that boron carbide boils above the b.p. of carbon. S. A. Tucker and H. J. W. Bliss add that it conducts electricity, and it has been utilized for electrodes by F. Bölling, in the construction of electric furnaces by E. G. Acheson, and for making lamp filaments by C. R. Böhm. According to H. Moissan, carbon hexaboride gives no carbon dioxide when heated in oxygen to 500°, and it burns slowly at 1000°, but more readily than the diamond, forming carbon dioxide and a black mass containing boric oxide. A. Joly found that when heated in chlorine, a residue of carbon mixed with a little aluminium and ferric chlorides is produced, and H. Moissan said that chlorine acts at 1000° without incandescence, producing boron chloride and black porous carbon. Under similar conditions, bromine and iodine have no action. Boron carbide was found by H. Moissan, and S. A. Tucker and H. J. W. Bliss, not to be attacked by any acid—indeed, the former said that boiling conc. hydrofluoric acid and nitric acid, alone or mixed, have no action, and when heated with fuming nitric acid for 4 hrs. in a sealed tube, there is but little action, and likewise also with a mixture of iodic and chromic acid; S. A. Tucker and H. J. W. Bliss found that a mixture of hot nitric acid and potassium chlorate, and boiling sulphuric acid have no action. H. Moissan, and S. A. Tucker and H. J. W. Bliss found that boron carbide is decomposed by molten potassium hydroxide with the evolution of carbon monoxide; it is also decomposed by a fused mixture of potassium and sodium carbonates.

O. Mühlhäuser claimed to have made *carbon monoboride*, CB, or C_2B_2, by heating a mixture of boric oxide and carbon in an electric furnace. The graphite-like mass was heated in a platinum crucible for 5½ hrs., powdered, boiled with hydrochloric acid, filtered, washed, again boiled with hydrochloric acid, and finally with a mixture of this acid and hydrofluoric acid. The black powder could scarcely be distinguished from graphite; *e.g.* it blackened the fingers like graphite, etc. Its analysis was represented by $B\equiv C-C\equiv B$. It behaves like H. Moissan's hexaboride towards reagents—*e.g.* at a higher temp. it becomes soft and melts; it burns with difficulty in oxygen; it is insoluble in nearly all the solvents; it is decomposed by fusion with alkali hydroxides or carbonates; and it is oxidized by heating it with lead chromate. Hence, added S. A. Tucker and H. J. W. Bliss, "O. Mühlhäuser actually obtained a mixture of carbide and graphite, owing to the difficulty of separating the latter; and he failed to obtain any large masses of the product because of the very high temp. necessary."

H. Moissan and A. Stock [8] heated one part of boron and five parts of crystalline silicon for about a minute in a vessel of refractory clay by means of an alternating current of 600 amps. and 45 volts. The cooled mass was treated with a mixture of nitric and hydrofluoric acids in order to remove excess of silicon, and the crystalline portion of the residue after heating with moist potassium hydroxide was extracted with dilute nitric acid and hot water and dried at 130°. The product consisted of a mixture of two borides, SiB_3 and SiB_6, containing about 80–90 per cent. of the latter. The hexaboride is readily oxidized by boiling nitric acid, whereas the triboride is only slowly attacked by this reagent; the latter compound, on the other hand, is decomposed by fused potassium hydroxide, whilst the former remains unchanged. **Silicon triboride,** SiB_3, forms black, rhombic plates which, when very thin, appear yellowish-brown by transmitted light; its density is 2·52. The **silicon hexaboride,** SiB_6, is always obtained in thick, black, opaque crystals with somewhat irregular faces; its density is 2·47. These silicon borides, like the boride and silicide of carbon, are very hard, being intermediate between the diamond and ruby in the scale of hardness; they are soluble in fused silicon and conduct electricity. When gently heated, they are decomposed by fluorine and are attacked at higher temp. by chlorine and bromine, but not by iodine or nitrogen. They become superficially oxidized by heating in air or oxygen. They are not affected by the haloid acids, but are slowly decomposed by boiling conc. sulphuric acid, and rapidly dissolved by fused potassium carbonate or by a mixture of this compound with potassium nitrate; the latter salt alone has no action on them. O. P. Watts did not succeed in making definite borides by the action of boron on silicon at a high temp.

H. Moissan obtained a diamond-hard **titanium boride** by heating the two constituents in an electric furnace. S. A. Tucker and H. R. Moody prepared

zirconium boride, Zr_3B_4, by heating a mixture of 15 grms. of zirconium with 2·2 grms. of boron, for 5 mins. in a carbon crucible with the aid of a current of 200 amps. and 65 volts. The product was a button, blackish on the outside, brittle, and of a steel-grey colour on fracture. Under the microscope, it proved to be an agglomeration of brilliant, tabular, translucent to transparent crystals, many of these being colourless. It had a sp. gr. 3·7 and a hardness 8. It was slowly attacked by hot conc. acids and aqua regia. Boiling liquid bromine attacked it feebly. E. Wedekind obtained what he regarded as *zirconium borocarbide* by reducing zirconia with boron in an electric furnace; black crystals separate from molten copper.

A. B. du Jassonneix[9] found no signs of the formation of a *tin boride* when the two elements are heated in an electric furnace; and H. Giebelhausen found that amorphous boron is not dissolved and is hardly wetted by molten lead or tin. No *lead boride* has been reported. E. Wedekind and K. Fetzer obtained a micro-cystalline mass by heating an intimate mixture of thoria and boron in a magnesia crucible at a high temp. According to A. B. du Jassonneix, if a mixture of thorium oxide and boron is heated for three minutes in a carbon boat in an electric furnace, with a current of 500 amps. and 100 volts, the mixture assumes a metallic appearance, and fusion occurs only after some minutes with a current of 700 amps. The hard bronze-yellow or red product contains masses of needles, and is slightly carbonized only in the vicinity of the boat. When treated with hydrochloric acid, a gas containing hydrogen and hydrocarbons is evolved; it burns with a green flame; and leaves a residue containing the tetraboride or a mixture of tetra- and hexa-borides. The product containing not more than 10–12 per cent. of boron furnishes a yellow metallic powder of **thorium tetraboride,** ThB_4, consisting of fragments of prismatic crystals and having a sp. gr. 7·5 at 15°. It is dissolved by cold conc. hydrochloric acid, by cold nitric acid with the formation of boric acid, or by hot sulphuric acid. Below a red heat, it is attacked by hydrogen chloride, by chlorine, or by sulphur with formation of boron and thorium sulphides, and it burns when slightly heated in contact with fluorine. The bronze-yellow to red product, containing over 12 per cent. of boron, contains a mixture of the borides from which the tetraboride is removed by extraction with conc. hydrochloric acid; the remaining **thorium hexaboride,** ThB_6, is an amorphous, reddish-violet, metallic substance which has a sp. gr. 6·4 at 15°, is not dissolved by conc. hydrochloric, hydrofluoric, or sulphuric acid, or by aq. alkali hydroxides, but dissolves easily in hot nitric acid and burns when slightly heated in fluorine. It is attacked by chlorine and oxygen below a red heat, by hydrogen chloride at a red heat, and forms boron and thorium sulphides when heated in sulphur vapour.

Boron reacts with nitrogen, forming boron nitride (*q.v.*); and with phosphorus forming boron phosphide (*q.v.*), but borides of the arsenic family have not been made. S. A. Tucker and H. R. Moody failed to make a *bismuth boride*. H. Giebelhausen found that boron is not dissolved and is hardly wetted by molten bismuth. H. Moissan first prepared crystalline chromic boride by heating the two elements in a carbon crucible in an electric furnace. O. P. Watts also made some impure chromium borides by heating a mixture of potassium dichromate, borax, calcium carbide, fluorspar, and aluminium in an electric arc furnace. S. A. Tucker and H. R. Moody obtained **chromium monoboride**—probably CrB—by heating a mixture of 10 grms. of chromium and 2·1 grms. of boron for 6 mins. in an electric furnace—175 amps., 60 volts. A product with the same composition was made by A. B. du Jassonneix by heating a mixture of chromium sesquioxide and boron and treating the product containing 16 per cent. of boron with hydrogen chloride or chlorine; and by E. Wedekind and K. Fetzer, by heating amorphous boron with chrome thermite mixture in a fire-clay crucible. S. A. Tucker and H. R. Moody's product was green and crystalline with a sp. gr. 5; E. Wedekind and K. Fetzer's product was silvery-white and crystalline, of sp. gr. 5·4 at 17°; and A. B. du Jassonneix' product had a sp. gr. 6·1 at 15°. This boride is hard; melts with difficulty;

conducts the electric current; and is feebly ferromagnetic. It does not change when heated in air, or in oxygen at a red heat. A. B. du Jassonneix found that it reacts with cold fluorine with incandescence; sulphur converts it into sulphide; when heated with nitrogen there is only a superficial action, forming a greyish-black substance which gives ammonia when fused with potassium hydroxide; and cold hydrofluoric, hydrochloric, and sulphuric acids react. E. Wedekind and K. Fetzer said that the dil. acids have no action, and that hydrofluoric acid, a mixture of hydrofluoric and nitric acids, and a mixture of nitric and hydrochloric acids act very slowly; hot conc. sulphuric acid is reduced to sulphur dioxide; and molten potassium hydroxide, nitrate, or chlorate acts feebly, but it is decomposed vigorously by sodium dioxide, forming chromate and borate. A. B. du Jassonneix found that **chromium ditritaboride,** Cr_3B_2, can be isolated from an alloy containing 11·6 per cent. of boron by the action of hydrogen chloride below a red heat, it has a sp. gr. 6·7 at 15°, burns in fluorine when gently heated, and is attacked with incandescence by chlorine below a red heat; the action of bromine is less vigorous, whilst iodine vapour has only a superficial action at a red heat. When heated in air or oxygen, it becomes covered with a vitreous layer of the borate; it is converted into a mixture of boron and chromium sulphides together with unchanged boron by the action of boiling sulphur; it is completely soluble in conc. or dil. hydrofluoric, hydrochloric, or sulphuric acid, and is oxidized with incandescence by fused alkali hydroxides or carbonates; it is not acted on by nitric acid or alkali soln., or by nitrogen at a white heat.

According to S. A. Tucker and H. R. Moody,[10] **molybdenum boride,** Mo_3B_4, is obtained by heating a mixture of the two constituent elements in an electric furnace for 20 mins. The crystalline mass has a sp. gr. 7·105; and hardness 9. It melts at a very high temp., and is not easily attacked by acids. O. P. Watts also made a soln. of molybdenum boride in a large excess of molybdenum, by heating in an electric arc furnace a mixture of molybdenite, boron oxide, and aluminium powder. H. Moissan prepared a **tungsten boride** which scratched glass by heating the two elements in an electric arc furnace, and S. A. Tucker and H. R. Moody obtained tungsten boride, probably WB_2, by fusing a mixture of the two elements in an electric arc furnace. The silvery product contained octahedral crystals of sp. gr. 9·6, and hardness 8. It was slowly attacked by conc. acids, and vigorously by aqua regia.

L. Troost and P. Hautefeuille [11] prepared small violet-grey crystals of **manganese diboride,** MnB_2, by heating manganese carbide with boric oxide in a carbon crucible: $Mn_3C+3B_2O_3+8C=3MnB_2+9CO$. C. Matignon and R. Trannoy obtained needle-like crystals by firing according to the thermite process an intimate mixture of manganese and boric oxides, and finely powdered aluminium in a crucible lined with magnesia; and O. P. Watts obtained a mixture of the two manganese borides by a similar process. A. B. du Jassonneix said that the product always contains aluminium from which it is purified by heating it in a stream of chlorine, and washing out the chlorine successively with ice-cold water, alcohol, and ether. The sp. gr. of the greyish-black or greyish-violet crystals, according to A. B. du Jassonneix, is 6·9, and that of boride, according to E. Wedekind, is 6·04 at 19°. The last-named found this boride melts when heated on a platinum foil, and there is some oxidation. According to L. Troost and P. Hautefeuille, the heat of formation is 2·487 Cals. per gram. E. Wedekind found that the powder compressed into a block does not conduct electricity, but it is strongly magnetic, and possesses considerable permanent magnetism. According to L. Troost and P. Hautefeuille, and E. Wedekind, this manganese boride is decomposed by water at 100°; and in the absence of water it is very stable; L. Troost and P. Hautefeuille said that the boride dissolves readily in acids with the evolution of hydrogen, while E. Wedekind said that conc. hydrochloric acid dissolves it only when heated, and that aqua regia attacks it slowly, otherwise, dil. acids, including acetic acid, dissolve the boride easily. L. Troost and P. Hautefeuille said that hydrogen chloride attacks the boride slowly at a red heat; and that alkaline soln. dissolve it slowly below 100°. Mercuric chloride quickly converts it into manganese chloride, boric acid, and hydrochloric acid; and mercury cyanide attacks it in the presence of water. A second compound, **manganese monoboride,** MnB, was prepared by A. B. du Jassonneix by reducing manganese oxide with an excess of boron in an electric furnace, and removing the accompanying products by treatment of the powdered material at a dark red heat with chlorine, following by washing first with water, and then with alcohol. E. Wedekind made it by a similar process; and O. P. Watts, by firing a mixture of aluminium, boric oxide, and manganese dioxide according to the thermite process. A. B. du Jassonneix said that the crystalline powder has a sp gr. of 6·2 at 15°. E. Wedekind found that it is strongly magnetic, and possesses considerable permanent magnetism. According to A. B. du Jassonneix, this boride burns in fluorine at the ordinary temp., is attacked by chlorine or bromine at a red heat, whilst the action of iodine at a high temp. is only superficial; it forms a fusible borate when heated in oxygen, is not attacked by nitrogen; it slowly decomposes, cold water forming magnetic hydroxide and boric acid; dissolves in dil. hydrochloric acid, and is attacked by hydrogen chloride or hydrogen fluoride, nitric or sulphuric acid; by the action of ammonia at 1000°, a compound is obtained which contains nitrogen, is not attacked by acids, and yields manganates and borates with evolution of ammonia on fusion with alkali carbonates. E. Wedekind found that warm conc. sulphuric acid is reduced to sulphur dioxide, and that conc. nitric acid attacks it at ordinary temp. with the evolution of red fumes.

H. Moissan [12] prepared **iron monoboride,** FeB, by the action of the vapour of boron chloride in reduced iron at a dull red heat, or by the direct union of iron and boron at 1200° in an atm. of hydrogen. If the temp. is too high, boron carbide will be formed. The product is heated with hydrochloric acid, and the residue washed successively with water, alcohol, and ether. C. Matignon and R. Trannoy prepared a mass of tough prismatic needles of iron boride by heating a mixture of ferric oxide, boric oxide, and aluminium in an electric furnace. According to H. Moissan, iron boride forms brilliant yellowish-grey crystals, sp. gr. 7·15 at 18°. Iron boride does not alter in dry air or oxygen, but in moist air it becomes covered with an ochreous layer. When heated in oxygen, it takes fire, and then burns brilliantly without further extraneous heat. In all cases, amorphous iron boride is much more readily attacked than the crystalline compound, and since the action of oxygen on the boride is greatly accelerated by the presence of moisture and carbonic anhydride, the incandescence sometimes observed during the drying of impure amorphous boron may be attributed to the presence of amorphous iron boride. It is attacked by chlorine at a red heat, with incandescence, and even more readily by bromine, with the formation of a double iron boron bromide, but iodine and hydrogen iodide have no action even at 1100°. Dil. hydrochloric acid has no action, but the hot conc. acid attacks the boride slowly. Hydrofluoric acid also attacks it slowly, whether hot or cold. The boride is attacked by sulphur and phosphorus at high temp. Potassium nitrate and potassium chlorate are without action at their m.p., but at higher temp. attack the boride with incandescence. Fused alkali carbonates and hydroxides decomposed it rapidly and completely. Conc. or dil. sulphuric has no action in the cold, but the boiling conc. acid converts it into ferrous sulphate with evolution of sulphurous anhydride. Very dil. nitric acid dissolves the boride only when hot, but the conc. acid attacks it with violence. When grey cast iron containing about 3·2 per cent. of carbon is strongly heated in a porcelain boat brasqued with boron and contained in a porcelain tube through which a current of hydrogen is passed, the boron displaces the carbon, which is reduced to 0·36–0·14 per cent., whilst at the same time the quantity of slag present in the iron is considerably reduced because the boron combines readily with the impurities. The residual iron contains 8 to 9 per cent. of boron. Similar effects are observed with white cast iron, the carbon in one case being reduced from 3·85 to 0·24 per cent., and the slag from 0·38 to 0·06 per cent. When cast iron containing 10 per cent. of boron is

ded to 10 times its weight of grey cast iron fused in a forge, there is still a notable isplacement of carbon, and the metal has a lamellar structure, is very hard, and esembles white cast iron in appearance.

A. B. du Jassonneix prepared two other borides by heating mixtures of iron, educed by hydrogen, and boron in a stream of hydrogen in a porcelain tube; the ne, **iron hemiboride,** Fe_2B, forms steel-grey prisms of sp. gr. 7·37 at 18°. It is xidized by dry air at a dull red heat, but is readily attacked by moist air at ordinary emp. It is dissolved by cold conc. nitric acid, and by hot dil. nitric acid, or hot hydrochloric or sulphuric acid. The other, **iron diboride,** FeB_2, contaminated with 2 per cent. of carbon boride, resembles cast iron, but is slightly yellow, and hard nough to scratch quartz. Its sp. gr. is 5·0 at 18°; it is oxidized by moist air; and dissolved by hot conc. hydrochloric or nitric acid, leaving the carbon boride as a residue.

The thermal diagram of the binary system iron and boron has been investigated by G. Hannesen, and N. Tschischewsky and A. Herdt, for mixtures with up to about 12 per cent. of boron. The former found the solubility of boron in iron to be greater than did the latter. Both agree that a compound **iron pentahemiboride,** Fe_2B_5, is formed which, according to G. Hannesen, melts at 1360°, and, according to N. Tschischewsky and A. Herdt, at 1325°. For the saturated mixed crystals, Fig. 6, the former obtained 0·25 per cent. of boron, the latter 0·08 per cent. The former gives 1165° for the eutectic, *E*, with 4 per cent. of boron, the latter give 1130° with 0·3 per cent. of boron. According to the former, the mixed crystals have a maximum boron content, *P*, of 0·8 per cent., the latter gave 3·5 per cent.; *G*, represents mixed crystals of iron boride with α-iron containing 0·25 per cent. of boron, according to the former, and 0·08 per cent. of boron, according to the latter. The former gave 720° for the decomposition temp., the latter gave 760°. The former gave 1400° for the transformation temp. of δ-iron into γ-iron, the latter gave 1320°. G. Hannesen alone gave a special curve for the transformation of γ-iron mixed crystals into β-iron mixed crystals. There is also evidence of the hemiboride. N. Parravano and C. Mazzetti prepared a boride by heating iron to 900° in an atm. of boron trichloride. H. W. Gillet and E. Mack studied the effect of boron on steel.

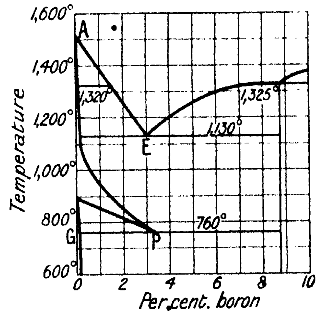

Fig. 6. - Freezing-point Curve of Mixtures of Iron and Boron.

H. Giebelhausen found that boron readily dissolves in molten nickel. H. Moissan prepared **nickel boride,** NiB, and **cobalt boride,** CoB, by heating their constituents in crucibles, brasqued with boron, in an electric furnace with a current of 300 amps. and 50 volts, or in a reverberatory furnace fed with gas carbon. The product is treated with dil. nitric acid, and the borides are obtained in brilliant prisms which are often several mm. long, are magnetic, and about as hard as quartz. The sp. gr. of the nickel compound is 7·39 at 18°, and of the cobalt compound 7·25. They are attacked by chlorine at a dull red heat, by bromine at a higher temp., and by iodine at the softening temp. of glass. They are not affected by dry air or oxygen, but alter rapidly in moist air, especially in presence of carbonic anhydride. Fused alkali chlorates, nitrates, hydroxides, or carbonates dissolve and decompose them; water vapour at a dull red heat converts them into oxides and boric acid, and acids, conc. or dil., attack them with varying degrees of readiness. The nickel and cobalt borides are analogous to the iron borides previously described, and may likewise be used for introducing boron into a metal such as iron. A. B. du Jassonneix prepared **cobalt hemiboride,** Co_2B, and **nickel hemiboride,** Ni_2B, as well as **cobalt diboride,** CoB_2, and **nickel diboride,** NiB_2, by methods similar to those employed with the corresponding iron compounds. A. Stock and E. Kuss obtained nickel hemiboride by the action of di- and tetra-boron hydrides on a soln. of a nickel salt. According to A. B. du Jassonneix, the product from cobalt and boron, containing about 5 per cent. of the latter, consists of an agglomeration of small, elongated, prismatic crystals; it is only very slowly attacked by hot hydrochloric acid, leaving a residue which is still less easily attacked. This consists of the boride Co_2B in the form of small, brilliant, steel-grey needles, with a sp. gr. 7·9 at 20°, which are violently attacked by nitric acid and slowly oxidized by moist air. The nickel mass, containing 5 per cent. of boron, has a microcrystalline structure, and is very slowly attacked by hot hydrochloric acid, but leaves no residue, and the compound Ni_2B is isolated by dissolving the excess of nickel electrolytically in nickel chloride soln. The boride forms small, very slender, yellow, acicular crystals, with a sp. gr. 8·0 at 20°, which are violently attacked by nitric acid and are slightly oxidized by long exposure to moist air. Borides of cobalt and nickel, containing more than 20 per cent. of boron, are more easily prepared in the electric furnace. N. Parravano and C. Mazzetti prepared a nickel boride by heating nickel to 900° in an atm. of boron trichloride.

H. Giebelhausen studied the f.p. curve of mixture of nickel with up to 20 per cent of boron, Fig. 7. The curve has maxima at 1225° and 1160°, corresponding with the compounds Ni_2B and Ni_3B_2 respectively, the latter of which undergoes a transformation at 1050°. A compound, NiB, is indicated at about 1020° without giving a maximum. The curve then rises rapidly, suggesting a maximum at the composition Ni_2B_3. Only the last of these compounds forms solid soln. and only the alloys containing free nickel are magnetic. The compound Ni_2B is slightly harder than quartz, whilst the compounds richer in boron are somewhat harder, but are scratched by topaz. The borides, FeB_2, CoB_2, and NiB_2, represent the superior limit of the combination of boron with the respective elements.

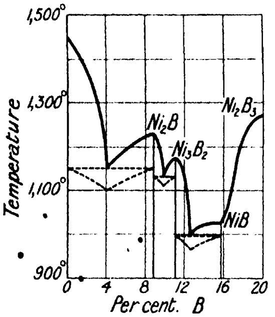

FIG. 7.—Freezing-point Curve of Mixtures of Nickel with up to 20 per cent. of Boron.

H. V. C. Descotils [13] fused platinum along with carbon and boric acid, and obtained what may have been a boride or a borocarbide. According to H. Moissan, when finely divided boric acid and potassium are heated in a platinum crucible, a considerable amount of platinum is taken up. F. Wöhler and H. St. C. Deville obtained a silvery-white **platinum boride** by heating platinum with boron. Cubic crystals of sp. gr. 17·32 have been found in the fused mass. The colour of the boride resembles platinum, and it can be readily ground to powder. The boride is very slowly soluble in aqua regia, and boric acid separates from the soln. Analyses by C. A. Martius agree with the formula Pt_2B_3. J. G. Rose reported the presence of platinum in borax, but E. G. Bryant showed that the borax was contaminated with an impurity.

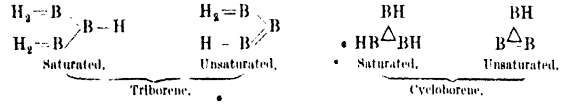
§ 5. The Hydrides of Boron or Hydroborons

There is no evidence of the direct union of hydrogen and boron, even at 1500°, although the union can be effected by indirect means, and quite a number of boron hydrides have been prepared. In 1810, H. Davy [1] noticed that when the mass obtained in the preparation of boron by the reduction of boric oxide with potassium, is treated with water or dil. hydrochloric acid, a gas is obtained which is mainly hydrogen, but it has a disagreeable odour, and burns with a blue flame tinged with green. He accordingly assumed that the hydrogen obtained in this way is mixed with a small quantity of a compound of hydrogen and boron. F. Wöhler and H. St. C. Deville (1858), and H. Moissan (1893) tried in vain to prepare a boron hydride by the action of dil. hydrochloric acid on aluminium boride, and by the direct union of the elements; and G. Gustavson (1870) likewise failed to make a boride of hydrogen by the action of sodium amalgam on boron trichloride at 150°, although silicon hydride can be obtained by the analogous reaction. V. C. Vournasos also obtained borurretted hydrogen by heating boric oxide with sodium and sodium formate, or with sodium formate alone. H. B. Baker and H. B. Dixon observed that boron occludes hydrogen with great tenacity.

In spite of F. Wöhler and H. St. C. Deville's failure, F. Jones (1878), and F. Jones and R. L. Taylor (1881) obtained hydrogen mixed with appreciable quantities of what was presumably boron hydride by treating magnesium boride with dil. hydrochloric acid. The results were confirmed by P. Sabatier (1891), who showed that although F. Jones and R. L. Taylor's gas contained but small traces of boron hydride, yet the amount sufficed to impart to the gas a disagreeab[illegible] smell; to make the hydrogen burn with a green flame; to make the gas give [illegible]wn precipitate, soluble in nitric acid, when bubbled through a soln. of silve[illegible]; to give a ring of boron when passed through a red-hot tube so that the [illegible] gas was free from boron; and to attack mercury, forming a brown solid. [illegible] supposed boron hydride is decomposed by treatment with potash lye, forming ordinary hydrogen with a slight increase in volume; it is also decomposed by a stream of electric sparks; by a soln. of potassium permanganate, etc. C. Winkler also obtained a similar gaseous product.

W. Ramsay and H. S. Hatfield (1901) found that F. Jones' gas could be dried by potassium hydroxide or phosphorus pentoxide, and be frozen to a white crystalline solid by cooling with liquid air. After removing the gases from the solid in vacuo, the crystals were warmed; they melted and vaporized, giving a gas with a fœtid odour and density 19·36, and which burnt in air with a green flame. The gas was decomposed by electric sparks, and the products gave analytical numbers in agreement with the formula B_3H_3, and it was called **triborene.** Further attempts to make the gas gave another one which, unlike the first, decomposed when treated with sulphuric acid, and with potassium hydroxide. The density was 18·1, and W. Ramsay and H. S. Hatfield therefore concluded that there are two isomers with the formula B_3H_3. This has been explained by assuming that there are four different gaseous triborenes, namely, saturated and unsaturated triborene, and saturated and unsaturated **cycloborene** with tervalent boron:



W. Ramsay and H. S. Hatfield found that, in the preparation of triborene, B_3H_3, the exit gases consisted of a mixture of hydrogen and boron trihydride. The latter was stated to be a colourless gas with an unpleasant and characteristic odour, and which, when inhaled, produced sickness and headache. It dissolves in water, and the soln. does not change on standing; it burns with a bright green flame, forming boron trioxide; and it is decomposed into its constituents at a red heat, or by electric sparks. It gives a black precipitate with silver nitrate which contains boron and silver, and which is decomposed by hot water with the evolution of boron hydride. When boron hydride is passed into ammonia, it acquires a fœtid odour, and burns with a yellow-green flame; and the characteristic smell of boron hydride reappears if the ammoniacal soln. is acidified; it unites with ammonia, furnishing a product which can be frozen to a white crystalline solid. The gas was not obtained pure, but when burnt with hot copper oxide, the analytical data correspond very nearly with **boron trihydride,** BH_3.

A. Stock and his co-workers have not been able to establish the existence of any these compounds; although qualitative evidence makes the existence of one or ore gaseous boron hydrides B_mH_n highly probable. In truth, a *mixture* of gaseous oron hydrides can be prepared under these conditions; but they add that the greement of the analytical figures of W. Ramsay and H. S. Hatfield with the ormula B_3H_3 appears rather as a chance coincidence.

There is also evidence of the existence of solid boron hydrides; for example, Reinitzer (1880) obtained a solid hydride by washing with hot water the mass btained by fusing boric oxide with potassium under a layer of sodium chloride; Winkler (1889), L. Gattermann, and W. Ramsay, and H. S. Hatfield found a solid ydride, which the two former believe to be B_8H, in the residue obtained by treating agnesium boride with boiling hydrochloric acid; H. Moissan (1893) obtained a olid hydride in the preparation of F. Wöhler and H. St. C. Deville's amorphous oron by treating the crude mass with distilled water instead of with hydrochloric acid; and R. Lorenz also found that boron prepared by reducing boric acid with sodium or potassium is invariably accompanied by a solid hydride. Formulæ like B_8H; $B_{3\cdot3}H$, etc., have been assigned to these products, but the evidence is far from satisfactory.

A. Stock and co-workers have studied the product of the action of acids on magnesium boride very closely. They obtained ten boron hydrides. Those corresponding with the series BH_4 are called *boranes*; thus, monoborane or simply borane is BH_4; diborane, B_2H_6; etc. The corresponding univalent radicle BH_3 is called monoboryl; the radicle BO, boroyl; and for the OH derivatives of the boranes the termination *ol* is used. Thus, B_2H_5OH would be *diboranol*. They found that the best yield of boron hydrides is obtained if magnesium boride be dropped, in small portions at a time, into sulphuric or hydrochloric acid not too dil.-say, two, four, or eight times normal between 40° and 50°. The isolation of the various hydrides is complicated by the presence of silicon hydrides, and this could not well be avoided since it was not found possible to make magnesium entirely free from silicon. The gaseous products are washed with water, dried by calcium chloride and phosphorus pentoxide, and condensed as far as possible by liquid air. The crude condensate is then fractionally condensed or distilled.

The apparatus is illustrated in Fig 8. The 4*N*-HCl is placed in a flask *A*, fitted (i) with a condenser *F* and exit tube *H*; (ii) a mercury safety valve *G*; and (iii) a coil *I* of lead tubing fed with water from the condenser. The neck of the flask *B* is fitted with a glass cylinder containing powdered boride to be gradually added to the acid in the flask *A*. The powder is continually agitated by the rotation of a metal tube fitted with lugs *ee* as shown in the diagram. The tube is joined to a rod which passes through the mercury seal *C* and is slowly rotated by the pulley *P* connected with a motor. A slow current of hydrogen passes through the tube and side-neck *D*, down the metal tube through an opening *k*, and into the flask *A*. The powder falls through the opening *m* at a rate which can be regulated by the speed of rotation of the central rod. The flow of gas can thus be regulated by the agitator. The gas is partially freed from water vapour (i) by the condenser *F*; then passes (ii) through the small wash-bottle containing water so that the bubbles can be counted; thence through (iii) a U-tube one half of which contains calcium chloride and the other half phosphorus pentoxide. The gas then passes through (iv) a U-tube receiver fitted with stopcocks, and cooled by liquid air; 100 grms. of boride give about 70 litres of gas, from which about 95 c.c. of the hydride B_4H_{10}, and 0·02 grm. of the hydride B_6H_{12} can be obtained.

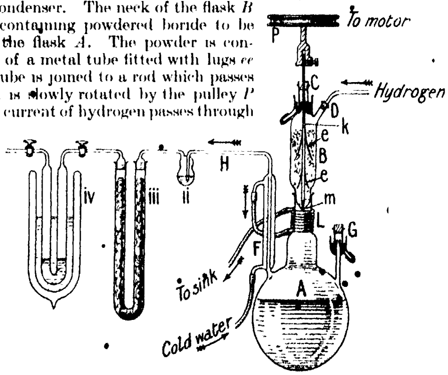


FIG. 8.—Stock's Apparatus for Preparing Boron Hydrides.

The condensed liquid readily decomposes, and it explodes when exposed to the air. The receiver is therefore fitted with another system of U-tubes, mercury gauge, and special tubes for receiving the particular fractions to be collected. The crude gas is passed through a tube cooled by liquid ammonia (between −45° and −35°) whereby white crystals of the solid $B_{10}H_{14}$ are collected; then through a large U-tube cooled by a mixture of acetone and solid carbon dioxide (between −82° and −75°) in which a little of the hydride B_4H_{10}, some silicon hydride, and much of the hydride B_6H_{12}, is condensed; and finally the main bulk of the gas is condensed with liquid air. The liquid can be freed from silicon hydride, carbon dioxide, phosphine, and hydrogen sulphide by reducing the press. to a few millimetres while the temp. is kept at about −80°. The liquid is then warmed to about 20° under a press. below 3 mm. when the more volatile hydride, B_4H_{10}, comes off. This hydride is removed by distilling the residue at −40° under a press. of about 1·5 mm., and the temp. is raised to 0° under a press. of 9 to 10 mm. The residue furnishes the decahydride B_6H_{12} when distilled, while the press. falls to 5 mm.

No *diborane*, B_2H_6, was found in the crude gas; and the production of *monoborane*, BH_4, or *triborane*, B_3H_8, could not be established. As just indicated, **tetraboron decahydride,** B_4H_{10}, or **borobutane,** is isolated from the products of the action of an acid on magnesium boride. It is a colourless liquid gas with a disagreeable smell. A few bubbles of the gas affect the respiration, and produce a headache. The compound is rather unstable and begins to decompose at the room temp. in a few hours, forming other boron hydrides. The vap. press. of the liquid at 6° is 580 mm.; at 10°, 630 mm.; at 15°, 710 mm.; at 16°, 740 mm.; and it boils between 16° and 17° (760 mm.). The solid melts at about −112°. This compound is rapidly decomposed when heated at 100°, forming three solid hydrides, and at a higher temp. it is resolved into its elements $B_4H_{10}=4B+5H_2$. Even at ordinary temp. the purified gas decomposes fairly quickly into hydrogen, diborane, and less volatile hydrides. It inflames spontaneously when exposed to air or oxygen. Vapour density determinations and analyses of the gas agree with the formula B_4H_{10}. This is also consistent with the products of the action of the gas on alkali-lye, or on water or dil. hydrochloric acid. This reaction can be symbolized: $B_4H_{10}+12H_2O=4B(OH)_3+11H_2$. Conc. nitric acid causes explosion, potassium permanganate soln. is rapidly reduced; and gaseous ammonia gives a brown solid insoluble in water and possibly **diamminoborobutane,** $B_4H_{10}.2NH_3$. Assuming that boron is quadrivalent, the constitution of this compound can be represented $BH_3.BH_2.BH_2.BH_3$—thus recalling the hydrocarbon butane, C_4H_{10}, or $CH_3.CH_2.CH_2.CH_3$.

Small quantities of **pentaboron enneahydride,** B_5H_9, are present in the higher boiling fractions of the crude condensate, but its isolation from this source is extremely difficult, and it is more readily obtained from the products of the decomposition of tetraborane at 100°. It is a colourless, mobile, not highly refractive liquid with an extremely unpleasant odour; it is the noxious component of the crude boron hydrides. It is slowly decomposed by water, but otherwise fairly stable. A. Stock and co-workers also isolated **hexaboron decahydride,** B_6H_{10}, from the crude condensate, as a colourless, moderately highly refractive liquid which is less mobile and not so unpleasant in odour as the other boron hydrides. It decomposes slowly when preserved in daylight at the atm. temp., giving small quantities of hydrogen and diborane and mainly a yellow crystalline solid, possibly **hexacosiboron hexatriacontihydride,** $B_{26}H_{36}$.

The action of dil. acid on magnesium boride, as indicated above, furnishes a gas whose analysis and vapour density agree with the formula for **hexaboron dodecahydride,** B_6H_{12}, or **borohexylene,** but the data are not sufficiently accurate to decide definitely the exact amount of hydrogen. This hydride is a colourless highly refracting liquid with an unpleasant odour, and is spontaneously inflammable in air. The vap. press. of the liquid at −40° is about 1 mm.; at 0°, 10 mm.; at 10°, 15 mm.; and at 24°, 25 mm. The liquid boils at about 100° (760 mm.). Hexaboron hydride readily decomposes, it becomes yellow in a short time, and finally deposits a solid. It is more resistant towards water and moisture than the tetraboron hydride. In contact with alkali-lye, hexaboron hydride gives off hydrogen, he tetraboron hydride does not. Assuming that boron is quadrivalent, the onstitution of this compound can be represented $BH_3.BH_2.BH$: $BH.BH_2.BH_3$.

When gaseous tetraboron decahydride is allowed to stand, it increases in volume nd forms gaseous, liquid, and solid products of decomposition. The gaseous roducts are hydrogen and **diboron hexahydride,** B_2H_6, or **boroethane, or diborane.** A convenient method of making this hydride is to heat the tetraboron hydride for bout four hours at 100°. The decomposition products are condensed by cooling in iquid air, and the fraction, pumped from the condensate and cooled between −125° nd −115° in a bath of alcohol and liquid air, is the hydride in question. Diboron exahydride is a colourless gas having a repulsive smell with a taint of the tetraboron ydride and hydrogen sulphide. The vap. press. of the liquid at −130° is 40 mm. ; t 100°, 400 mm. ; and it boils between −87° and −88° (760 mm.). The solid nelts at −169°. When heated with a naked flame it forms a colourless and yellow olid boron hydride, but unlike B_4H_{10}, it forms no liquid products. The yellow solid ublimes in vacuo, and the same solid is formed by heating the tetraboron hydride, B_4H_{10}, and it probably has the composition $B_{10}H_{14}$. Analyses of the gas and vapour density determinations agree with the formula B_2H_6 ; and this is confirmed by the products of its explosion with oxygen : $B_2H_6+3O_2=B_2O_3+3H_2O$; and the action of water : $B_2H_6+6H_2O=2H_3BO_3+6H_2$. Assuming that boron is quadrivalent this compound may be constituted $H_3B.BH_3$, thus resembling the hydrocarbon ethane, C_2H_6, or $CH_3.CH_3$. The diboron hydride is more stable than the tetraboron hydride. It does not fire spontaneously in air unless contaminated with other boron hydrides. It reacts with alkali-lye like the tetraboron hydride. The diboron hydride is soluble in carbon disulphide, and the soln. decolorizes bromine, forming hydrogen bromide. It does not react with dry hydrogen chloride, but it forms crystalline products with ammonia. Diboron hexahydride explodes in contact with chlorine at ordinary temp. ; bromine reacts slowly in light, and the action is complete at 100°. The hydrogen is replaced by the halogen. An excess of halogen gives the simple trihalides BCl_3 and BBr_3, and not B_2Cl_6 and B_2Br_6. When diboron hydride was treated with about one-third of the theoretical quantity of bromine required for complete substitution, the intermediate products $BHBr_2$, BH_2Br, $B_2H_2Br_4$, B_2HBr_5, $B_2H_4Br_2$ were not observed, but B_2H_5Br and BBr_3 were obtained. Probably small quantities of other intermediate products were formed, but soon rearranged themselves to form B_2H_5Br and BBr_3 as shown by the increase in the vapour density of the mixture at ordinary temp.—indeed, B_2H_5Br itself decomposes into B_2H_6 and BBr_3 in a short time. The instability of these haloid substitution products is significant ; and A. Stock (1914) uses the fact that these boron hydrides, and their haloid substitution products appear to be sat. as an argument in favour of the assumption that the maximum negative valency of boron is four. **Diboron monobromohydride,** B_2H_5Br, is a colourless fuming gas with an irritating odour. The vap. press. of the liquid at −80° is 3 mm. ; at −40°, 53 mm. ; at −10°, 255 mm. ; and it boils at about 10° (760 mm.). It burns with a pale green flame. The monobromide reacts with water as symbolized : $B_2H_5Br+3H_2O=B_2O_3+HBr+5H_2$. Like the hydrides B_2H_6, it also reacts with alkali-lye, forming hypoborates, but it does not react appreciably with sodium. The analogous **diboron monochlorohydride,** B_2H_5Cl, is more volatile and less stable than the bromo-derivative ; it is a spontaneously inflammable gas.

A mixture of three solid hydrides is formed by heating B_2H_6 for 48 hrs. at 115° to 120°, or the tetraboron hydride at 100° for 4 or 5 hrs. A longer heating at a higher temp. lessens the yield. One of the three hydrides, **decaboron tetradecahydride,** $B_{10}H_{14}$, is volatile, the other two are non-volatile ; and of the latter, one is colourless, the other yellow ; the yellow non-volatile solid is insoluble in carbon disulphide, and it can therefore be separated from the colourless non-volatile solid which is soluble. This yellow non-volatile solid is insoluble in water, and *probably* contains about 4 atoms of hydrogen to 5 of boron—B_5H_4. When heated it gives a number of boron hydrides poor in hydrogen, which have not been further studied. The colourless non-volatile hydride is soluble in carbon disulphide, stable in water, and forms a yellow soln. with soda-lye. It probably contains 12 *atoms of boron in the mol. It decomposes when heated, forming a liquid hydride.*

The mol. wt. of the volatile solid in benzene soln. agrees with the formula $B_{10}H_{14}$. Decaboron tetradecahydride is a colourless solid with a penetrating odour. When heated in vacuo it forms long colourless needle-like crystals, of sp. gr. 0·94, which melt sharply to a clear liquid at 99·5°. It is soluble in carbon disulphide, alcohol, ether, and benzene, but is not attacked by water, for it floats in a molten condition on boiling water at 100°. Dil. soda-lye dissolves the solid hydride, forming a solid soln. It is reduced by potassium permanganate, and is slightly attacked by nitric acid. The fused mass begins to decompose at 200°, forming yellow products. The vap. does not decompose to any appreciable extent in a short time at 400°, but at 600° it decomposes into its elements boron and hydrogen. Bromine and chlorine react sluggishly with the solid decaboron hydride, $B_{10}H_{14}$, not additively, for the hydrogen is replaced by the halogen. When the solid hydride is allowed to stand in contact with an excess of bromine for about six months, the product, on evaporation, furnishes a residue with a composition ranging between $B_{10}H_{12}Br_2$ and $B_{10}H_{11}Br_3$, and the separated individuals were isolated by fractional crystallization from a mixture of benzene and light petroleum. The alkaline soln. of these bromo-derivatives, when acidified, yields tetraboron decahydride, B_4H_{10}. Both the acidic and alkaline soln. reduced potassium permanganate; the former gradually evolves tetraboron and other hydrides which have not been identified.

The di- and tetraboron hydrides, B_2H_6 and B_4H_{10}, dissolve in sodium hydroxide, forming soln. which contain hypoborates, and which gradually decompose, forming borates. A. Stock and E. Kuss (1914) conclude that the first stage of the reaction is in accord with the equation: $B_4H_{10}+4NaOH=H_2+4NaOBH_3$; and the second stage $B_4H_{10}+4NaOH+4H_2O=4NaBO_2+11H_2$. The last-named reaction occurs rapidly when the soln. is warmed. **Potassium hypoborate,** $KOBH_3$, was obtained in octahedral, colourless, deliquescent crystals by treating a soln. of potassium hydroxide with an excess of tetraboron hydride at 0°. In the presence of moisture, the hypoborates decompose at room temp. in accord with the equation: $2KOBH_3+2H_2O=2KBO_2+5H_2$. The hypoborates are strong reducing agents, stronger indeed than hypophosphites and give precipitates with most salts, but insoluble hypoborates have not yet been prepared. With copper salts, copper hydride is formed, and with nickel salts an insoluble black nickel boride, Ni_2B. Potassium hypoborate dissolves in alcohol with partial decomposition. At 500°, it partially decomposes into potassium, hydrogen, water, etc.: $10KOBH_3=2K_3B_5O_3+4K+4H_2O+11H_2$. The resulting $K_3B_5O_3$ is hygroscopic. The aq. soln. has an alkaline reaction; slowly decolorizes potassium permanganate; and gives a yellowish-brown coloration to warm nitric acid. With sulphuric acid, it gives hydrogen and boron hydrides. The aq. soln. obtained by treating magnesium boride with water has properties similar to that of a soln. of $K_3B_5O_3$. **Sodium hypoborate** resembles the potassium salt; **magnesium hypoborate** could not be isolated from soln. The failure to obtain a boron hydride with a single boron atom, analogous with the boron trihalides, and with the boron alkyls, $B(CH_3)_3$, etc., is significant. Triphenylmethyl, $C(C_6H_5)_3$, has been reported, but no carbon trihydride CH_3 is known, hence, the fact that $B(CH_3)_3$ is known does not definitely prove that BH_3 can likewise exist. The failure may be due to our ignorance of the right conditions for its preparation, or because BH_3 is so very unstable that if it were momentarily formed, it would immediately polymerize to B_2H_6, just as E. Frankland (1862) found that boron ethyl above 149° has a vapour density in agreement with the formula $B(C_2H_5)_3$, but below 101·6°, there are signs of a polymerization to $B_2(C_2H_5)_6$.

A. Stock emphasized the peculiarities shown by the boron hydrides in furnishing formulæ which are not explained by simple and constant valencies; the great affinity of boron for oxygen which is shown by the ready decomposition of the hydrides by water; the inclination of the molecules to polymerize to form hydrides of high mol. wt., and non-volatile oxides and nitrides; and the instability of compounds containing positive and negative radicles—*e.g.* the compound B_2H_5Cl decomposes into a hydride and a chloride. A. Stock considered that in B_2H_6, B_4H_{10}, B_6H_{12}, $B_{10}H_{14}$ the boron is quadrivalent. M. L. Maurice assumed that the double-bonded atoms of boron have a greater tendency to form and maintain complexes than carbon atoms, and that the residual affinity of this double-bond is strong enough to hold hydrogen atoms, but is incapable of holding larger atomic nuclei. He then proposed a structural formula for B_2H_6 analogous to ethylene; one for B_4H_{10} analogous to butylene; one for B_6H_{12} analogous to benzene; and one for $B_{10}H_{14}$ analogous to naphthalene.

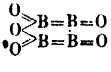
§ 6. Boron Oxides

The behaviour of boron towards oxygen has already been discussed. C. Winkler[1] believed that only one oxide is formed, namely, boron trioxide, B_2O_3. The evidence in favour of the existence of a **boron suboxide,** previously discussed, is not satisfactory. A. Stock and E. Kuss prepared a class of salts which they call *hypoborates vide* boron hydrides. M. W. Travers and co-workers believe that they have established the independent existence of a *tetraboron trioxide*, B_4O_3; of acidic *diboron dioxide*, B_2O_2; and of *tetraboron pentoxide*, B_4O_5; in addition to the ordinary *boric oxide*, B_2O_3, but the products they obtained were very impure.

Boron dioxide, B_2O_2, has not been isolated in a pure state. It was prepared by decomposing crude magnesium boride with cold water and the soln. evaporated to dryness in vacuo and heating. The residue is a mixture of dioxide with the magnesium salt **magnesium borite,** $MgO.2B_2O_2$, or MgB_4O_5. Boron dioxide is obtained free from magnesium borite, but contaminated with about 5 per cent. of a lower oxide, $B_4O_3.2H_2O$, by treating the aq. soln. of magnesium boride with ammonia, and evaporating the filtered soln. The product is soluble in water, and the aq. soln. is oxidized to boric oxide, by evaporating it in air, or by heating it with nitric acid, but is not oxidized by iodine. The lowering of the f.p. of aq. soln. corresponds with the formula B_2O_2. The oxide seems to combine with water to form an acid, which dissolves freshly precipitated magnesium hydroxide to form magnesium borite. Attempts to make ammonium borite were not satisfactory.

As already indicated, an impure dihydrated **tetraboron trioxide,** $B_4O_3.2H_2O$, has been obtained from the product of the action of water on magnesium boride; it is soluble in nitric acid with the formation of boric acid. When dried at 100°, analyses correspond with the formula just indicated. When magnesium diborohexahydroxide, $Mg_3B_2(OH)_6$, is treated with conc. ammonia for several days in an atm. of hydrogen, filtered, evaporated to dryness in vacuo, and heated, a pale brown **tetraboron pentoxide,** B_4O_5, is formed.



It does not fuse at the softening temp. of Jena glass. If allowed to stand in contact with water in vacuo, a yellow soln. is obtained, which oxidizes rapidly in air, forming a flocculent yellow residue containing tetraboron trioxide : $3B_4O_5+2H_2O=B_4O_3.2H_2O+4B_2O_3$.

M. W. Travers and co-workers showed that when crude magnesium boride is treated with water **magnesium diborohexahydroxide,** $Mg_3B_2(OH)_6$, is formed : $Mg_3B_2+6H_2O=3H_2+Mg_3B_2(OH)_6$, which remains as a white insoluble powder. It appears to be a derivative of $H_6B_2(OH)_6$, and, by analogy with the *carbohydrates*, is *regarded* as one member of a series of **borohydrates.** *When treated with conc. ammonia in an atm. of hydrogen, it* is assumed that the soluble product of the reaction is a diammonium derivative of $BH_2(OH)_2.BH(OH).BH(OH).BH_2(OH)_2$; and that when this product is acidified it loses four atoms of hydrogen, and forms $BH(OH)_2.B(OH).B(OH).BH(OH)_2$, which loses more hydrogen when treated with iodine, forming two mols of hydrogen iodine and $B(OH)_2.B(OH).B(OH).B(OH)_2$. When the ammoniacal soln. is evaporated in vacuo, and heated, tetraboron pentoxide is formed : $BH_2(OH)_2.BH(OH).BH(OH).BH_2(OH)_2=5H_2+H_2O+B_4O_5$.

The soln. obtained by the action of water on magnesium boride is yellow because it contains colloidal boron ; it decomposes slowly at ordinary temp. with the evolution of hydrogen, and the decomposition is accelerated if platinum black be present ; it precipitates silver and mercury from their salts ; it precipitates amorphous boron or copper hydride from copper salts ; and when acidified, it gives off hydrogen with brisk effervescence and the liquid so obtained decolorizes iodine. The soln. is supposed to contain a very small proportion of borohydrates or allied compounds which are produced by unknown side reactions in the action of water on magnesium boride.

M. W. Travers and co-workers assume that the soln. contains two compounds with quinquevalent boron, and with the formulæ $H_6B_2O_2$ and $H_6B_2O_3Mg$; and that the latter is a magnesium derivative of $H_8B_2O_3$. The graphic formulæ are based on the assumption that the evolution of hydrogen is due to the elimination of pairs of hydrogen atoms attached directly to atoms of boron :

$$\begin{array}{lll} H_2 & B & -OH \\ H_2 & \ddot{B} & -OH \end{array} \qquad\qquad \begin{array}{lll} H & -B- & (OH)_3 \\ H & -B & H_3 \end{array}$$

When treated with acids, these compounds furnish respectively

$$\begin{array}{l} H_2BOH \\ H_2\ddot{B}OH \end{array}\ \begin{array}{l} B.OH \\ B.OH \end{array} + 2H_2 \qquad\qquad \begin{array}{l} HB(OH)_3 \\ HBH_3 \end{array}\ \begin{array}{l} B(OH)_3 \\ BH_3 \end{array} + H_2$$

The compound HO.B:B.OH has a structure analogous with that of hyponitrous acid. The two products are oxidized by iodine to boron dioxide, B_2O_2 :

$$\begin{array}{l} B.OH \\ \dot{B}.OH \end{array} + I_2 = \begin{array}{l} B:O \\ \dot{B}.O \end{array} + 2HI \qquad\qquad \begin{array}{l} BH_3 \\ \ddot{B}(OH)_3 \end{array} + 2I_2 = \begin{array}{l} B:O \\ \dot{B}:O \end{array} + 4HI + H_2O$$

When the soln. obtained by the action of water on magnesium boride is treated with ammonia, magnesium hydroxide is precipitated. When the **magnesium borohydrate,** $MgH_6B_2O_3$, or possibly $MgH_4B_2O_2.H_2O$, is treated with ammonia, the new product, when acidified, gives twice as much hydrogen as before. It is assumed that intramolecular change occurs as an intermediate stage of the reaction :

$$\begin{array}{l} H\dot{B}(OH)_3 \\ HBH_3 \end{array} \rightarrow \begin{array}{l} H_2\dot{B}(OH)_2 \\ H_2BH(OH) \end{array} \rightarrow \begin{array}{l} B(OH)_2 \\ \dot{B}H(OH) \end{array} + 2H_2$$

The product is oxidized by iodine to boron dioxide, B_2O_2 ; *i.e.* $O:B.B:O$, or

$$\begin{array}{c} O.B:B.O \\ |\qquad\quad | \end{array}$$

P. C. Ray isolated **potassium borohydrate,** $(KO)_2B_2H_4$, from the soln. obtained by the action of water on magnesium boride. It is also formed when magnesium boride is treated with a dil. soln. of potassium hydroxide. Conductivity determinations show that it is the salt of a dibasic acid. The action of iodine on acidified soln. is represented: $H_4B_2(OK)_2+2H_2SO_4=2KHSO_4+2H_2+B_2(OH)_2$; and $B_2(OH)_2+I_2=B_2O_2+2HI$. The constitution of the salt is represented by

$$\begin{array}{l} H_2:B.OH \\ H_2:\ddot{B}.OH \end{array} \quad \text{or} \quad \begin{array}{l} H_2:B.OH \\ H_2:\dot{B}.OH \end{array}$$

according as boron is quinque- or quadri-valent. The salt is fairly stable in the absence of moisture and carbon dioxide; it is a powerful reducing agent; and is highly soluble in water. The salt loses four atoms of hydrogen when treated with an acid, forming **diboron dihydroxide,** HO.B : B.OH.

§ 7. Boron Trioxide, Boric Oxide, or Boric Anhydride

Boric oxide is formed when H. Moissan's boron is heated in air or oxygen, or in nitric oxide; the same oxide is formed in the combustion of boron hydride; and when boron is employed as a reducing agent with the dioxides of carbon, silicon, titanium, or zirconium. H. Henstock discussed its electronic structure.

The usual method of making boron trioxide is to melt boric acid in a platinum or Hessian crucible until all is tranquil, showing that the water has been expelled. The molten mass is poured on to a cold slab. The resulting boron trioxide, called *vitreous or glassy boric acid*, is preserved in well-stoppered bottles. A. Atterberg[1] and others have also described its preparation, by heating the hydrate. According to P. G. Robiquet, the product still retains 0·225 per cent. of water, which he said can be removed only by ignition with cupric oxide. R. Lorenz also made observations on the rapidity with which water is absorbed by boric oxide. If one portion of the clear glass is rapidly powdered in a hot mortar, and the powder is immediately heated in a small dried test-tube, it melts with bubbles under conditions where a piece not powdered melts without bubbling. This does not necessarily prove, as R. Lorenz supposes, that water is so rapidly imbibed by the powder, but rather, in melting, a skin is formed over the surface of the powder before the air entangled in the powder has escaped. R. Lorenz added that the fused oxide is so strongly hygroscopic that it can take up 1·9 per cent. of water during one minute's trituration in a hot mortar.

Boric oxide so formed is a colourless, transparent glass which is hard and brittle. H. Davy[2] said that it has no smell, and that it has a slightly bitter, not an acid taste. The **specific gravity** of boric oxide was given by A. Royer and J. B. A. Dumas as 1·83 at 4° in vacuo; G. Quincke gave 1·83 at 0° and 1·75 at 1300°; P. A. Favre and C. A. Valson gave 1·825 at 216°; A. Ditte gave 1·8766 at 0°; 1·8476 at 12°; and 1·6988 at 80°; P. P. Bedson and W. C. Williams gave 1·848 at 14·4°, and 1·853 at 15·8°. K. Arndt and A. Gessler found the sp. gr. at 900° to be 1·520; at 1000°, 1·508; and at 1100°, 1·495. V. de Luynes said the **hardness** of the glass is great; it scratches glass and is scarcely affected by quartz. K. Arndt found the **viscosity** of boric oxide to be 118·0 at 900° and 40·0 at 1100° (water at 20°=0·01). G. Quincke stated that its **surface tension** in air at 1700° is 847 dynes per cm., and its **specific cohesion** is $a^2=9{\cdot}865$ sq. mm.

According to A. Ditte, the coeff. of **thermal expansion** is 0·001308 between

12° and 80°. G. Quincke gave 1300° for the **melting point**, and T. Carnelley gave 577° approximately. The truth is that the glass has no m.p.; it is a congealed liquid which has never solidified, but has become as viscid that it appears even harder than many crystalline compounds—*vide* 1. 9, 6. The hardness of the glass can be readily augmented by quick cooling; and if the molten glass be poured on a cold metal plate, the lower face contracts faster than the upper face, which is more slowly cooled. In consequence, the plate is bent and it finally shivers into fragments. According to J. B. A. Dumas, when the molten oxide is cooled in a platinum crucible it cracks spontaneously and glows along the cracks with a light which is visible even in daylight. C. L. Bloxam said that boric oxide is slightly volatile at a bright red heat; F. Wöhler and H. St. C. Deville, that it volatilizes at the m.p. of nickel, or, according to J. J. Ebelmen, at the highest temp. of a porcelain oven; and H. Moissan found that it readily volatilizes in the electric furnace. W. R. Mott gave 1500° for the **boiling point** of boric oxide at 760 mm. H. von Wartenberg and O. Bosse found that at 1501° and 138 mm. boric oxide did not boil, and that the molten mass had the viscosity of olive oil; they could not measure the **vapour pressure** of boric oxide at 1536°–1546°. The **specific heat** was found by H. V. Regnault to be 0·2574 between 16° and 98°. M. Berthelot gave for the **heat of formation**, $B+\frac{1}{2}O_3=\frac{1}{2}B_2O_3+156,300$ cals., and L. Troost and P. Hautefeuille gave 317·2 Cals. for the mol. heat of formation. The former also gave for the **heat of hydration**, $B_2O_3+3H_2O+400H_2O$ at 13·5° $=-9\cdot62$ Cals. P. A. Favre and C. A. Valson gave 122·731 Cals. per eq. of B_2O_3.

According to V. de Luynes, molten boric oxide acts strongly on polarized light, P. P. Bedson and W. C. Williams found that a prism of boric acid with the *D*-line had an **index of refraction** 1·46303 and sp. gr. 1·848 at 14·4°; and another at 15·8° had an index of refraction 1·46427 and sp. gr. 1·853. The index of refraction of soln. of sp. gr. 1·0111 at 20° with 1·93 per cent. of B_2O_3 was 1·0096 at 20° with a 1·68 per cent soln. According to E. Tiede and co-workers, if boric acid is dehydrated either in the air or in a vacuum over phosphoric oxide, either slowly at 300° or quickly at red heat, it exhibits a **phosphorescence**, the intensity of which reaches a maximum with a certain, minute proportion of water still present, but disappears as full dehydration is attained. The exceptionally bright light emitted does not continue for long, and may be excited by an arc or mercury lamp, but not by cathode X-rays, radium rays, or by heat. E. Tiede and P. Wulff found that the phosphorescence of partly dehydrated boric acid originates from traces of organic compounds, and is removable, not by recrystallization, ignition in a stream of oxygen, boiling with nitric acid, or fusion with potassium nitrate, but by boiling with fuming nitric acid for twenty-four hours, subsequently recrystallizing three times from water specially purified, and finally igniting the upper portion of the filtered mass (which had not been in contact with filter-paper) in a platinum crucible. Phosphorescence would not be induced in such a product by any means other than by introduction of organic impurities. For this purpose, even those present in ordinary distilled water suffice. It is presumed that the phosphorescence emanates from definite organic derivatives of boric acid. Boric acid phosphorescent compounds were studied by R. Tomaschek. E. H. Nichols and D. T. Wilber found boric oxide showed a dim flame **luminescence.**

According to H. Davy, moist boric acid conducts electricity; but, according to M. Faraday, the acid, fused in the oxy-hydrogen blowpipe, "gained no conducting powers sufficient to affect the galvanometer, and it underwent no apparent voltaic decomposition"; A. Connell also confirmed this observation. M. Lapschin and M. Tichanowitsch also found that molten boric oxide did not conduct a current at 950 volts; and W. Hampe, and L. Bleekrode also classed boric oxide acid as a bad conductor. H. Moissan said that the presence of 20 per cent. of borax makes the acid a conductor. G. Meslin found that boric oxide is diamagnetic.

E. Davy, and J. L. Gay Lussac and L. J. Thénard made rough analyses of boric oxide. J. J. Berzelius' analyses were originally interpreted on the assumption that the at. wt. of boron corresponded with the oxide BO_6 (oxygen 8), later, the at. wt. was halved, and J. J. Berzelius, A. Payen, and E. Soubeiran wrote the formula BO_3; when the at. wt. of oxygen was doubled, this became B_2O_3. *The tribasicity of ordinary boric acid*, orthoboric acid, has been established by the formation of the esters trimethylborate, $B(OCH_3)_3$, and triethylborate, $B(OC_2H_5)_3$, by J. J. Ebelmen and M. Bouquet; of methyldifluoborate, $BF_2(OCH_3)$, and ethoxydifluoborate, $BF_2(OC_2H_5)$ by V. Gasselin; and of a number of metal borates by J. J. Ebelmen, L. Ouvrard, etc. M. Prokofieff also emphasized the analogy between the formula of boric acid and of the methyl esters. O. Hehner supposed boric acid to be constituted $H_4B_4O_8.H_2O$. E. Beckmann found the mol. wt. of boric oxide in boiling sulphuric acid to correspond with the value calculated for B_2O_3.

According to J. E. Myers, when boron trioxide is placed in water, even if it be in a finely ground condition, it does not dissolve immediately. After the trioxide has been in contact with water for a minute or two, a reaction takes place quite suddenly, and is marked by a notable change in the vol. of the solid. The solid produced dissolves fairly quickly in water. The phenomenon is best observed by exposing the substance to a moist atm. when there is a gradual and easily observed change from the hard glassy material to a light powdery substance. The boron trioxide is hydrated to metaboric acid, HBO_2, and orthoboric acid, H_3BO_3. J. E. Myers studied the velocity of hydration of boron trioxide, and found the reaction occurs in at least two stages, the first yielding metaboric acid and on further hydration orthoboric acid. The hydration to metaboric acid is a unimolecular reaction and much faster than the further reaction. The dehydration of orthoboric acid at 100° is a unimolecular reaction resulting in the formation of metaboric acid. At a higher temp. the reaction becomes more complicated, probably on account of the formation of mol. complexes of metaboric acid. According to A. Ditte, during the dissolution of boric oxide in water, so much heat is evolved that the temp. can be raised to the b.p., and P. A. Favre and C. A. Valson found that the dissolution is attended by a contraction of 16·2 c.c. per eq. B_2O_3. The aq. soln. colours litmus a faint red, and in the presence of mineral acids, turmeric paper becomes reddish-brown; if the dried paper is dipped in a dil. soln. of potassium hydroxide, K. Kraut showed that a blue colour is developed. According to L. Kahlenberg and O. Schreiner, boric oxide, B_2O_3, immediately forms boric acid, H_3BO_3, when dissolved in water, but O. Hehner thinks that the behaviour of the aq. soln. towards turmeric shows that it dissolves as B_2O_3 and not as H_3BO_3, because the aq. soln. colours turmeric paper a pale rose colour, but the colour becomes intense if a trace of mineral acid is present, and turmeric paper sat. with a soln. of boric acid becomes red on exposure to air.

Boric oxide was found by H. Moissan[3] to react at ordinary temp. with **fluorine** very energetically and with *une vive incandescence de brilliantes étincelles*, forming boron fluoride and oxygen. L. Gmelin found that while **bromine** and **chlorine** do not act on heated boric oxide, if the latter be mixed with carbon, the corresponding boron halide and carbon monoxide are formed. J. Inglis obtained an analogous result with **iodine.** J. J. Berzelius found that **hydrofluoric acid** converts boric oxide into the fluoride; G. Gore also obtained a similar result with liquid **hydrogen fluoride,** but not with liquid **hydrogen chloride.** J. Nicklès studied the action of **hydrogen bromide** and of hydrogen chloride on an alcohol soln. of boric oxide. According to H. St. C. Deville and H. Caron, when boric oxide is heated with **metal fluorides,** boron fluoride and crystals of the oxide are formed. When boric oxide mixed with silica-free **calcium fluoride,** with or without sulphuric acid, is heated to whiteness, J. L. Gay Lussac and L. J. Thénard observed the formation of boron fluoride and calcium borate. The reaction has also been studied by J. Davy, G. Ferrari, and S. G. Rawson. L. Ouvrard studied the action of the oxides of calcium, strontium, barium, magnesium, zinc, cadmium, manganese, and nickel on a mixture of boron oxide and **potassium hydrofluoride.** J. L. Gay Lussac and L. J. Thénard said that **chlorides** do not decompose boric oxide at a white heat, but H. le Chatelier obtained *calcium chloroborate*, $3CaO.B_2O_3.CaCl_2$, by adding calcium oxide and boric oxide to molten **calcium chloride** ; and L. Ouvrard made observations on this subject. A. J. Balard found that boric oxide does not decompose **potassium bromide** at a red heat, but if moisture be present, hydrogen bromide and potassium borate are formed. L. Ouvrard made needle-like crystals of *calcium bromoborate*, $3CaO.5B_2O_3.CaBr_2$, by melting boric oxide with **calcium bromide.** H. Schulze found boric oxide to be without action on **potassium iodide,** but if air be present, C. F. Schönbein found that the iodide is decomposed at its m.p. L. Ouvrard did not succeed in making *calcium iodoborate* analogous with the corresponding chloro- and bromo-salts, by melting boric oxide with **calcium iodide.**

According to J. F. A. Göttling, when a mixture of **sulphur** with boric oxide burns, the flame is tinted green. According to L. Gmelin, and E. Frémy, **carbon disulphide** attacks a heated mixture of boric oxide and carbon, forming carbon monoxide and boron sulphide. H. Prinz found that **sulphur monochloride,** S_2Cl_2, *is without action on boric oxide.* R. F. d'Arcy observed no signs of a reaction with **sulphur trioxide,** but A. Pictet and G. Karl said that two compounds are formed, $B_2O_3.SO_3$ and $B_2O_3.2SO_3$. According to L. Gmelin, H. Schiff, and G. Merz, boric oxide dissolves copiously in **sulphuric acid,** especially at an elevated temp., and furnishes a viscid mass from which water precipitates boric oxide. J. J. Berzelius found that selenium dioxide is expelled from **selenites** when they are heated with boric oxide.

When boric oxide is heated in a stream of **ammonia,** L. Möser and W. Eidmann found that boron nitride, BN, is formed: $B_2O_3+2NH_3=2BN+3H_2O$; likewise also, according to H. Rose, with a mixture of boric oxide and **ammonium chloride.** L. Gmelin found that red-hot barium borate is not attacked by the vapour of **phosphorus.** G. Gustavson found that no action occurs when boric oxide is heated for two weeks at 200° with **phosphorus trichloride** ; while boron oxychloride and boron trichloride are formed with **phosphorus pentachloride** ; and the double chloride, $POCl_3.BCl_3$, is formed if **phosphoryl chloride,** $POCl_3$, is used; with **phosphorus pentabromide,** boron tribromide is formed with difficulty; while **phosphorus tetraiodide,** P_2I_4, and **phosphorus triiodide,** PI_3, have no action.

According to L. Gmelin, **carbon** at a white heat has no action on boric oxide. E. Tiede and E. Birnbräuer found that a carbide is formed which sublimes in threads. The reduction occurs at 2400°. H. Quantin found a mixture of **carbon monoxide** and chlorine does not attack boron oxide; and H. Quantin, E. Demarçay, P. Camboulives, and L. Meyer and R. Wilkins found **carbon tetrachloride** has no action. W. H. Balmain showed that when calcined with **potassium cyanide,** boric oxide is converted into the nitride; and M. Darmstadt obtained a similar product with **urea.** The affinity of boric oxide or boric acid for the bases is but little greater than that of carbonic oxide, or carbonic acid; but when heated, L. Gmelin showed that it expels all acids more volatile than itself; thus, N. Tate showed that it expels the acid from **carbonates, nitrates,** and in part from the sulphates. The gas is expelled from the **carbonates** when they are heated with boric oxide, and the product behaves as a mixture of boric and metal oxides, as shown by C. H. Burgess and A. Holt. L. Ouvrard, etc. H. Schiff found that when boric oxide is warmed with absolute **alcohol,** some passes into soln., forming in a sealed tube at 120°, boric acid, H_3BO_3, and triethylborate, $B(OC_2H_5)_3$, a reaction previously studied by J. J. Ebelmen and M. Bouquet. V. C. Vournasos reduced boric oxide to boron by heating it with **sodium formate.** P. Schützenberger found that boiling **acetic anhydride** dissolves a large proportion of boric oxide; the reaction was also studied by A. Pictet and A. Geleznoff. A. Wohl and C. Neuberg, and G. Lockeman and O. Liesche investigated the action of boric oxide on **glycerol.**

J. L. Gay Lussac and L. J. Thénard found that a heated mixture of **potassium** and boric oxide decomposes with incandescence; **sodium** acts similarly without incandescence. A. Stock and W. Holle found that reduction likewise occurs with **calcium,** but calcium boride, CaB_6, is formed. As indicated in connection with the preparation of boron, boric oxide is readily reduced when heated with **magnesium.** The reaction with powdered **aluminium** conducted by the thermite process was found by F. E. Weston and H. R. Ellis to furnish a product difficult to isolate, and it is not suited for the preparation of boron. J. S. C. Wells found that **platinum** is appreciably attacked at high temp. by fused boric oxide. C. L. Bloxam reported that when **sodium hydroxide** or **barium hydroxide** is melted with a mol of boric oxide, three mols of water are expelled: $B_2O_3+6NaOH=2Na_3BO_3+3H_2O$; and with **potassium hydroxide,** two mols are driven off: $B_2O_3+4KOH=K_4B_2O_5+2H_2O$. W. Guertler studied the solubility of the **metal oxides** in fused boric oxide; he divided them into groups: I. The oxides of the five alkali metals, thallium, and silver dissolve in all proportions, and the soln., on cooling, furnish clear glasses if the proportion of boric oxide is high, and crystalline masses if the proportion of metal oxide is high. II. The oxides of copper (ous), lead, bismuth, antimony, arsenic, titanium, molybdenum, tungsten, and vanadium furnish, at 1400°, clear glasses which on cooling separate into an emulsion of two liquids, which on further cooling solidify. III. The oxides of the metals of the three alkaline-earths, magnesium, zinc, cadmium, manganese, iron (ous), cobalt, nickel, cerium, lanthanum, neodymium, praseodymium, samarium, and gadolinium, are not mutually soluble in all proportions at 1400°, but give a mixture of two liquids. Several of these are said to form borates, e.g. W. Guertler said that cerium forms $Ce_2O_3.B_2O_3$, but this H. Holm denied. C. H. Burgess and A. Holt found that calcium, strontium, barium, zinc, cadmium, magnesium, manganese, lead, and bismuth oxides are insoluble in small quantities, but, on gradually increasing the amount, dissolve to clear glasses; with a further addition of oxide, the mass again becomes opaque except in the cases of lead and bismuth, which yield pale yellow, very fusible glasses. The oxide of mercury appears to be soluble, and those of antimony and arsenic slightly so. The oxides of aluminium, beryllium, zirconium, tin, cerium, thorium, columbium, and silicon are all quite insoluble. The oxides which colour the borax bead, namely, those of chromium, copper, molybdenum, uranium, iron, nickel, and cobalt, are all insoluble in the fused anhydride, manganese in this respect behaving exceptionally. The last series of oxides can, however, be dissolved in boric anhydride containing lithium, potassium, cæsium, rubidium, and thallium, and the clear glasses obtained with large amounts of the coloured oxides are similar to the borax beads, although the colours are sometimes modified. W. G. Mixter said that boric oxide unites with **sodium dioxide** to form sodium orthoborate. L. Wöhler and W. Becker found that when boric oxide is heated with **ammonium dichromate**, Guignet's green, $Cr_4O_3(OH)_6$, is obtained free from boric oxide; with **potassium dichromate** and an excess of boric oxide, the product has the composition $Cr_4O_3(B_4O_7)_3$. K. Arndt and A. Gessler found the sp. gr. and eq. conductivity at 900° of various fused mixtures of boric acid and **sodium metaphosphate,** $NaPO_3$, to be:

Per cent. $NaPO_3$ . . .	100	50	25	10	5	1	0·5
Sp. gr. at 900° . . .	2·144	2·115	1·820	1·655	1·585	1·552	1·522
Conductivity . . .	49·5	16·4		-	1·55	--	0·67

K. Arndt also measured the viscosities. The solvent action of boric oxide has been utilized in opening up **silicates** for analysis.[4]

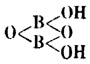
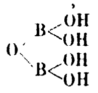
§ 8. The Boric Acids

As previously cited, T. Bergman, in his *De attractionibus electiris* (Upsala, 1775), clearly recognized the acid nature of " borax acid " and compared its affinity with that of other acids. Theoretically, boric anhydride should furnish the acids represented by :

Boric anhydride.



Metaboric acid



Mesoboric acid

Orthoboric acid.

Meta- and ortho-boric acids have been obtained, but not mesoboric acid, and the researches of J. J. Ebelmen and M. Bouquet[1] show that the first two acids are definite compounds. According to A. Holt, no clear evidence can be found for the existence of any acid containing less water than metaboric acid. Only orthoboric acid can exist in soln., under which conditions it is present in simple mols. Metaboric acid cannot be regarded as an equimolecular mixture of orthoboric acid and boric anhydride. Fused mixtures of orthoboric acid and boric anhydride, in which the mol. ratio of the latter to the former compound exceeds 4 : 1, can exist in a vitreous metastable and a crystalline form. Salts of the meta- and ortho-acids, the meta- and ortho-borates, are known, and also a number of salts with a higher proportion of acid. H. Rose said that the acid salts may be regarded either as mol. compounds of boric acid and the borates, or, better, as condensed acids formed by the removal of water from two or more mols of orthoboric acid, for boron, like carbon, exhibits a tendency to form complex mols. These condensation products form the so-called *polyboric acids* and polyborates—*e.g.* diborates, triborates, tetraborates, etc. Excepting, possibly, tetraboric acid, the polyboric acids have not been isolated although their salts are known. H. le Chatelier assumed that there are four types of borates, derivatives of the acids H_3BO_3, $H_6B_4O_9$, $H_4B_2O_5$, and HBO_2. R. Benedikt classed the different borates as salts of polyboric acids indicated in Table I.

TABLE I.—POLYBORIC ACIDS AND POLYBORATES.

Acid.	Formula.	Origin.	Reported salts.
Orthoboric . .	H_3BO_3	—	Mg
Metaboric . . .	$H_2B_2O_4$	$2H_3BO_3$ $2H_2O$	Li, K, Na, Ba, and Mg
Dihydrodiboric . .	$H_4B_2O_8$	$2H_3BO_3$ H_2O	Na
Hexahydrotetraboric .	$H_6B_4O_9$	$4H_3BO_3$ $3H_2O$	Na
Dihydrotetraboric .	$H_2B_4O_7$	$4H_3BO_3$ - $5H_2O$	Borax, etc
Hexahydrohexaboric .	$H_6B_6O_{12}$	$6H_3BO_3$ $6H_2O$	None
Dihydrohexaboric .	$H_2B_6O_{10}$	$6H_3BO_3$ $8H_2O$	Li, K, and Mg
Hexahydro-octoboric .	$H_6B_8O_{15}$	$8H_3BO_3$ $9H_2O$	Na and Mg
Dihydro-octoboric .	$H_2B_8O_{13}$	$8H_3BO_3$ — $11H_2O$	NH_4 and Na
Dihydrodecaboric .	$H_2B_{10}O_{16}$	$10H_3BO_3$ $14H_2O$	Li, Na, and K
Dihydrododecaboric .	$H_2B_{12}O_{19}$	$12H_3BO_3$ - $17H_2O$	K, Na, Ba, Sr, Mg, and Al

J. J. Berzelius prepared what was once called *pyroboric acid*, $H_6B_4O_9$, or $2B_2O_3.3H_2O$, which may be regarded as **tetraboric acid**, by heating orthoboric acid to 100°, until half the contained water is lost. G. Merz doubted the individuality of the product. The sodium salt of this acid, sodium tetraborate, $Na_6B_4O_9$, was made by A. Arfvedson by melting borax with sodium carbonate whereby two mols of carbon dioxide are driven off per mol of borax ; $Na_2B_4O_7+2Na_2CO_3=2CO_2+Na_6B_4O_9$. L. Kahlenberg and O. Schreiner reported **dihydrotetraboric acid**, $H_2B_4O_7$, or $2B_2O_3.H_2O$, to be formed by heating orthoboric acid to 140° ; or, according to J. J. Ebelmen and M. Bouquet, to 160° in a stream of dry air ; or, according to A. Atterberg, to 100° for a week. R. Nasini and J. Ageno said that this acid is produced when orthoboric acid is heated between 138° and 140°. The brittle glassy mass forms orthoboric acid when treated with water. It can also be regarded as the second anhydride of tetraboric acid, $H_6B_4O_9$. *Dehydrated borax*, $Na_2B_4O_7$, is then regarded the sodium salt of this acid, and can be called sodium metatetraborate.

$$\mathrm{{HO \atop HO}\!>\!B.O.\overset{OH}{B}.O.\overset{OH}{B}.O.B\!<\!{OH \atop OH}}$$

Hexahydrotetraboric acid, $H_6B_4O_9$.

$$\mathrm{HO-B\!<\!{O \atop O}\!>\!B-O-B\!<\!{O \atop O}\!>\!B-OH}$$

Dihydrotetraboric acid, $H_2B_4O_7$.

C. Zulkowsky represented the structure of dihydrotetraboric acid by the graphic formula just indicated. G. T. Gerlach said 100 grms. of water dissolve 2·69 grms. of $H_2B_4O_7$ at 15°, and the soln. has a sp. gr. 1·015. G. Merz reported the hydrate $8B_2O_3.H_2O$, or *dihydrohexadecaboric acid*, $H_2B_{16}O_{25}$, to be formed by heating orthoboric acid to 270°; and A. Atterberg the hydrate, $3B_2O_3.H_2O$, or *dihydrohexaboric acid*, $H_2B_6O_{10}$, by heating orthoboric acid for a week to 140°. There is, however, nothing to indicate that these two products are chemical individuals.

The first anhydride of orthoboric acid, **metaboric acid,** $B_2O_3.H_2O$, or HBO_2, or (HO)BO, was obtained by G. Merz,[2] F. G Schaffgotsch, C. L. Bloxam, H. Lescœur, and L. Kahlenberg and O. Schreiner, by the expulsion of a mol of water from one of orthoboric acid at 100°; A. Atterberg worked at 80°; and R. Nasini and J. Ageno, between 107° and 108°. P. Tschijewsky said that if boric acid be volatilized in a current of steam at 100°, crystals of metaboric acid appear where the steam condenses. O. Hehner said that at 100°, orthoboric acid does not lose two-thirds of its water, but vaporizes itself as such. According to H. Lescœur, the vap. press. of orthoboric acid becomes insensibly small when metaboric acid is formed. Metaboric acid is stable above 100°, and at 200° it forms a viscid mass which has a perceptible vap. press. too small for measurement. J. Thomsen gave for the heat of neutralization ($H_2B_2O_4$aq., 2NaOHaq.)=20·01 Cals.; and L. Kahlenberg and O. Schreiner found the heat of soln. in water to be positive, that of orthoboric acid is negative. H. Menzel gave for the ionization constant, $HBO_2 \rightleftharpoons H^{\cdot}+BO_2'$, $5{\cdot}7\times10^{-10}[HBO_2]=[H^{\cdot}][BO_2']$. The transport number of the BO_2'-ions in 0·05N-soln. was found by R. Abegg and A. J. Cox, J. Walker and W. Cormack, and H. S. Shelton to be nearly the same as for acetate ions. L. Kahlenberg and O. Schreiner found that water immediately converts metaboric acid into orthoboric acid. R. Nasini and J. Ageno found the mol. wt. in glacial acetic acid to be 38·3, when the value calculated for HBO_2 is 44; P. Walden stated that in aq. soln. the electrical conductivities of borax and of sodium metaborate are similar, and hence suggested that metaboric acid is dibasic, $H_2B_2O_4$, but P. T. Muller said that the abnormal conductivity is due to hydrolysis, and that the formula of the metaborates is MBO_2. C. Zulkowsky, however, used the graphic formula:

$$\mathrm{HO-B\!<\!{O \atop O}\!>\!B-OH}$$

P. Tschijewsky believed that **mesoboric acid,** $H_4B_2O_5$, or $HBO_2.H_3BO_3$, or $B_2O_3.2H_2O$, is formed as a compound which is volatile with steam, and which appears in crystals when molten boric acid is cooled.

The discovery of boric acid by G. Homberg[3] in 1702, and the occurrence of boric acid in the waters of the lagoons of Tuscany has already been discussed. G. Homberg's preparation was first called *sal sedativum*, and it was some time before it was recognized to be **orthoboric acid,** H_3BO_3. This acid is generally understood when the term *boric acid* or *boracic acid* is employed. This acid is formed by the action of water, steam, or alkali-lye on boron sulphide, or boron nitride; and, as already indicated, hypotheses as to the origin of boric acid in the fumaroles of Tuscany have been based upon these reactions. The boron halides are also hydrolyzed by water into boric acid and the corresponding haloid acid—*vide infra*. F. Landolph showed that boron hydrofluoride, $BF_3.HF$, is decomposed by atm. moisture with great rapidity. F. Jones and R. L. Taylor found boron hydride is oxidized to this acid by a soln. of potassium permanganate. J. L. Gay Lussac and L. J. Thénard, and H. Moissan showed that nitric acid converts boron into boric acid; and B. Reinitzer found that when finely divided, well-washed boron is left between filter paper in moist air for 8–10 days, it becomes covered with microscopic crystals of boric acid. R. Lorenz also demonstrated the extraordinary avidity of boric oxide for water whereby it is converted into boric acid.

The preparation of orthoboric acid.—The sources of commercial boric acid are the naturally occurring acid in the soffioni of Tuscany; native borax or tincal; boronatrocalcite, or Chilian borate of lime; pandermite from Asia Minor (*Turkish boracite*) and Stassfurtite, *i.e.* boracite.

(1) *From borax.*—Boric acid was formerly obtained by sublimation from a mixture of 16 parts of borax, 5 of sulphuric acid, and 2 of water, heated in a retort; the powdered residue was frequently moistened with water and again ignited. The yield was small. It is more conveniently made by treating a soln. of one part of borax in four parts of boiling water with one-third the quantity of sulphuric acid; on cooling the soln., boric acid crystallizes out, and a further quantity can be obtained by evaporating and cooling the soln. This is virtually G. Homberg's original process for *sal sedativum*. W. Meissner[4] evaporated the mixtures of sulphuric acid and boric acid to dryness, and extracted the boric acid with hot alcohol. H. W. F. Wackenroder preferred hydrochloric acid to sulphuric acid because the latter adheres more tenaciously to the separated boric acid; and E. Reichardt decomposed the soln. of borax with an excess of hydrochloric acid, evaporated the mixture to dryness at 100°, and extracted the sodium chloride with the smallest possible amount of water.

(2) *From the Tuscany fumaroles.*—Up to the end of the eighteenth century, boric acid was obtained industrially almost exclusively from borax. In 1775, U. F. Hoefer,[5] and P. Mascagni discovered boric acid in the waters of the Tuscany lagoons of Monte Rotondo and Castelnuovo; and shortly afterwards it was found in the solid state by P. Mascagni, at Sasso hence D. L. G. Karsten's name *sassolin*, which was afterwards changed to *sassolite*. U. F. Hoefer discussed the possibility of the extraction and utilization of the boric acid. The boric acid fumaroles and lagoons of Tuscany appear at the distance like clouds of vapour rising from the rugged mountains. They cover an area of about 30 sq. miles. In the vicinity, jets of boiling water seem to burst explosively from the earth, and voluminous clouds of steam rush into the atmosphere. The ground is hot, and is covered with crystalline sulphur and other minerals; the atm. smells of sulphurous oxide. The temp. of the water may be as high as 105°. The place was formerly regarded by the peasants as the veritable entrance to Hell, a superstition no doubt derived from ancient times, for the neighbouring volcano still bears the name Mons Cerberi or Monte Cerboli. A photograph of a boric acid lagoon at Volterra is shown in Fig. 9.

To recover the boric acid, it is merely necessary to evaporate the condensed vapours from the fumaroles. In 1807 G. Gazzeri's analyses led him to conclude that the quantity of boric acid contained in the waters was too small to promise successful extraction on a large scale. Undeterred by this, attempts were made at Monte Rotondo, in 1815, to extract the acid on an industrial scale by the evaporation of the liquor, but the cost of fuel (charcoal) required for the evaporation was prohibitive; about 1828 F. de Larderel happily conceived the idea of applying the heat from the soffioni to evaporate their own waters instead of wasting itself in the air. There are establishments at Castelnuovo, Monte Rotondo, Serrazzano, Lustignano, Larderello, Monte Cerboli, San Federigo, Sasso, and Lago, each operating 10 to 40 lagoons. The process of extraction is comparatively simple.[6]

Native steam issues from numerous blow-holes or soffioni in the ground in the neighbourhood of Larderello (Monte Cerboli district); it contains up to one-tenth per cent. of boric acid. The vents are lined with about 8-inch pipes extending into the earth from a few feet to over 300 ft. Some of the blow-holes are artificial, for they have been produced by boring and thus resemble artesian wells. The temp. of the issuing steam varies from 98° to 140°. Circular basins, about 30 ft. diameter, are built about the soffioni so as to include two or three vents, as shown diagrammatically in Fig. 10. A series of such basins, $A_1, A_2, \ldots A_7, A_8$, Fig. 10, are built at different levels on the side of a hill so as to form a kind of terrace of artificial lagoons. The uppermost one is filled with water from the mountain streams. The hot vapours bubble through the water producing a turbulent fountain several feet in height. The hot vapours give up their boric acid and raise the temp. of the water. In about 24 hours, the impregnated water is run into the next lagoon where a second impregnation occurs

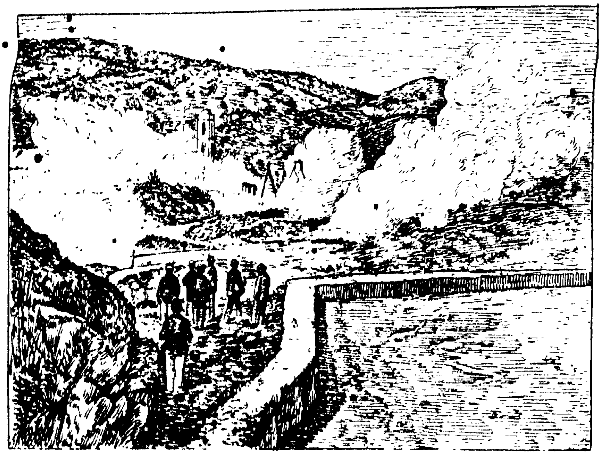


FIG. 9. Boric Acid Lagoon at Volterra.

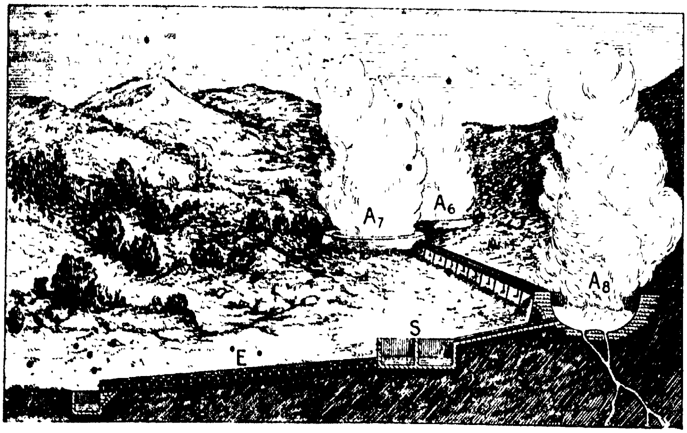

FIG. 10.—The Extraction of Boric Acid from the Soffioni in Tuscany.

In another 24 hours the liquid passes on to the third lagoon, and so on until it has reached the last of the series. The water will then have gathered about 2 per cent. of boric acid. If impregnation is allowed to proceed further, boric acid will be carried off with the escaping steam. The soln. is then allowed to settle in a rectangular settling-tank, S, Fig. 10, where fine mud containing more or less boric acid is deposited. This mud is used by country people for treating the skin diseases of cattle. The water from the settling-tank is allowed to run down a series of corrugated lead-lined evaporating troughs, E—6 ft. wide, 150 ft. long, and 8 ins. deep—heated by vapours from the soffiom. The liquid enters at one end and runs over the corrugations, where it is rapidly evaporated. If the temp. rises much above 50°, there is a loss of boric acid with the vapour. Any further evaporation, if needed, is conducted in leaden pans. When conc. to the point of crystallization—about sp. gr. 1·116 at 15°—the liquid is transferred to wooden crystallizing vats—10 × 30 sq. ft.—and allowed to cool. The mother liquor is returned to the evaporation pans. The crystals of boric acid are removed by wooden scoops, drained in baskets, and dried on a floor heated by native steam. The boric acid is shipped in casks containing about 1000 lbs. each.

According to O. L. Erdmann,[7] the Tuscany boric acid so prepared contains 3·18 per cent. of ammonia; and, according to G. C. Wittstein's analysis of a specimen in 1810,

H_3BO_3	$(NH_4)_2SO_4$	NH_4Cl	$MgSO_4$	$CaSO_4$	Na_2SO_4	K_2SO_4	$Fe_2(SO_4)_3$	$Al_2(SO_4)_3$
76·494	8·508	0·298	2·632	1·018	0·917	0·369	0·365	0·320

together with a combination of boric and sulphuric acids 1·322; silica, 1·200; combined water, 6·447; and traces of manganese sulphate and organic matter. The data may have been accurate to the first decimal. Another analysis by A. Scheuer (1892) is:

B_2O_3	H_2O	NH_3	K_2O	CaO	MgO	$Fe_2O_3 + Al_2O_3$	Cl	H_2SO_4
46·47	42·03	1·23	0·72	0·40	0·83	0·28	0·66	7·04

This is equivalent to 82·31 per cent. of boric acid. The Tuscany acid is refined by dissolving it in water heated by blowing in steam, and adding freshly ignited charcoal. The filtered soln. furnishes colourless crystals. M. Clouet purified the acid by heating it with nitric acid or sodium nitrate. Boric acid can also be still further purified by converting it into borax, purifying that by recrystallization, and subsequently converting the borax into boric acid again by adding hydrochloric acid to the hot soln. The resulting crystals of boric acid can be purified by crystallization from water.

The mother liquor remaining after the extraction of crude boric acid is called *salaccio*; it contains ammonium, magnesium, and sodium sulphates in addition to boric acid. U. Sborgi recovers the boric acid by boiling the salaccio with sodium carbonate, ammonia, and carbon dioxide, and concentrating for the crystallization of borax. The mother liquid is used as a source of sodium sulphate in the Dresel process for borax.

Boric acid is converted into borax by adding the necessary quantity of sodium carbonate to the aq. soln., and crystallizing. In the E. Dresel and J. Lenhoff's process[8] for making borax from boric acid and sodium chloride or sulphate, a soln. of boric acid and the alkali salt is subjected to the action of ammonia: $4H_3BO_3 + 2NH_3 + 2NaCl = Na_2B_4O_7 + 2NH_4Cl + 5H_2O$, a reaction which recalls the Solvay process for sodium carbonate. The reaction has been investigated by U. Sborgi and C. Franco at different temp. There are two invariant points in the system, and it is in the neighbourhood of one of these, corresponding to a solid phase composed of ammonium borate, borax, and ammonium chloride, that the best conditions for the practical working of the process are found. At 10° C. these conditions are obtained with an initial mixture in the proportions, $NaCl$ 393 grms., H_3BO_3 654 grms., NH_3 89·95 grms., H_2O 1206 grms. The quantity of crystallized borax precipitated is 941 grms., and the mother liquor contains 282·3 grms. NH_4Cl, 35·37 grms. $Na_2B_4O_7$, and 84·36 grms. $NaCl$ per 1000 grms. of water. The yield of precipitated borax is eq. to a recovery of 73·3 per cent. of the sodium and 93·4 per cent. of the boric acid in the initial mixture.

(3) *From the calcium and magnesium borates.* Boric acid is obtained from pandermite and other calcium borates by suspending the powdered mineral in water and adding sulphuric acid. A current of steam is blown into the liquid, so that the boric acid dissolves and the calcium sulphate is converted into a compact form which

is readily separated. The temp. is not allowed to rise over 80° or some boric acid will be lost in the vapour. The filtered liquid is cooled and allowed to crystallize. The crystals are purified if necessary by re-crystallization. F. Gutzkow[9] used a similar process with boronatrocalcite, and further discussed by G. Lunge, J. B. Hobson, F. Filsinger, and G. Krause. Hydrochloric acid can be used instead of sulphuric acid. P. Marquart and H. Schulz patented the use of carbon dioxide, the gas from lime kilns, etc., under press. for converting powdered boronatrocalcite suspended in water into calcium and sodium carbonates and boric acid; sulphur dioxide, or sodium hydrosulphite was also substituted for carbon dioxide. These processes have been discussed by J. Winkler. A. Schuster and M. Wilhelmy proposed hydrofluoric acid; R. Rickmann and E. Rappe, silicon tetrafluoride, sodium fluosilicate, or hydrofluosilicic acid: $2CaB_4O_7+SiF_4=4B_2O_3+2CaF_2+SiO_2$; M. Chenal and M. Douilhet, ammonium chloride; and C. C. Moore, chlorine: $3Ca_2B_4O_8+6Cl_2+18H_2O=12H_3BO_3+5CaCl_2+Ca(ClO_3)_2$. A. Partheil and J. Rose proposed extracting the boric acid from residues with ether, acetic ether, or chloroform. E. Becchi described methods for extracting boric acid from serpentine and related rocks.

The physical properties of orthoboric acid.—Boric acid crystallizes from hot aq. soln. in lustrous, colourless, flexible, six-sided plates which feel greasy to the touch. According to W. H. Miller,[10] the crystals are of larger size when they separate from a soln. containing sulphuric acid, etc., than from water alone as solvent. The **crystals** are triclinic pinacoids with the axial ratios and angles, according to K. Haushofer, $a:b:c=1\cdot7329:1:0\cdot9228$, and $\alpha=92°\ 30'$; $\beta=104°\ 25'$; and $\gamma=89°\ 49'$. Measurements have also been made by W. H. Miller, A. des Cloizeaux, G. d'Achiardi, and A. Kenngott. The **hardness** on Mohs' scale is 3. The **specific gravity** of the crystal, according to R. Kirwan, is 1·479; F. Stolba gave 1·4347 at 15°; P. A. Favre and C. A. Valson, 1·493 at 20·5°; and, according to A. Ditte:

	0°	12°	14	60°	80°
Sp. gr.	1·5463	1·5172	1·5128	1·4165	1·3828

The value calculated from B_2O_3 and solid water is 1·3003. According to P. A. Favre and C. A. Valson, the contraction during the crystallization of an eq. of boric acid is 9·3 c.c. E. F. Anthon gave 1·014 for the sp. gr. of a sat. aq. soln. at 8°; F. Stolba, 1·0248 for a soln. sat. at 15°; and P. A. Favre and C. A. Valson, 1·0106 for a N-soln. at 20·2°, and the contraction on soln. is 6·9 c.c. O. Bock gave for the sp. gr. of aq. soln. at 18°/4°:

Per cent. H_3BO_3	0·78	1·92	2·88	3·61
Sp. gr.	1·0029	1·0073	1·0109	1·0131

L. W. Oholm measured the **diffusion** of boric acid in aq. soln. from 18° to 20°, and found the coeff. k to be:

Conc. of soln.	1·5N	N	0·5N	0·1N	0·05N
Coefficient	0·813	0·816	0·826	0·876	0·954

F. Auerbach found the **elastic modulus** of crystals of boric acid to be 2030 kgrms. per sq. mm. For the elastic number—the ratio of the transverse contraction to the longitudinal extension—R. Straubel gave 0·28, and F. Auerbach, and R. Straubel gave 79·3 kgrms. per sq. mm. for the **torsion modulus** of the crystals of boric acid.

According to A. Ditte, the coeff. of **thermal expansion** of crystalline boric acid is 0·0015429 between 12° and 60°. H. V. Regnault gave 0·3535 for the **specific heat**; and T. Carnelley, 184°–186° for the **melting point**; it will, however, be obvious that this number does not apply to orthoboric acid. Not all are agreed as to the action of heat on boric acid. J. A. Rose observed no loss in weight when boric acid is dried in vacuo over conc. sulphuric acid. E. Löwenstein also observed no loss at 25°, when the acid is confined over 97 per cent. sulphuric acid. H. Lescœur found that boric acid formed by the hydration of boric oxide lost at ordinary temp. over sulphuric acid; 0·35 per cent. the first day, 0·08 per cent. the second day, and 0·00 per cent. the third day.

F. G. Schaffgotsch said that it is converted to metaboric acid, HBO_2. G. Merz said that no water is lost by heating it to a temp. of 70°, and that two-thirds is lost at 100°, and that it forms dihydrotetraboric acid, $H_2B_4O_7$, at 160°. At a higher temp., the acid froths up, losing its water, and forming a fused viscid mass of anhydride (*q.v.*), which on cooling congeals to a transparent but fissured glass. The formation of different hydrates has already been discussed. At a red heat, boric acid loses all its water and this is attended by much bubbling. H. Lescœur said that the acid is stable up to 100°, but at that temp. it has an appreciable vap. press. and slowly loses weight. In 1702 G. Homberg distilled ferrous sulphate with borax and found the distillate contained what is now known to be boric acid. G. Merz, F. G. Schaffgotsch, J. A. Rose, R. Bunsen, and H. Lescœur noted that the loss of the water of crystallization is attended by the vaporization of some boric oxide, and P. Tschijewsky found that a gram of the acid containing:

Grms. water of crystallization lost . . .	0·7808	0·7543	0·2783
Volatilized B_2O_3 per grm. of water . . .	0·1405	0·1358	0·1032

O. Hehner said that at 100° it vaporizes as H_3BO_3, G. Watson as HBO_2. P. Tschijewsky believes that the cause of the **volatility** is the formation of a volatile compound with water, just as the high volatility of boric oxide in the presence of methyl or ethyl alcohol is due to the formation of the corresponding esters. F. G. Schaffgotsch found much boric acid is lost during the evaporation of aq. soln. L. de Koningh said that this only applies with conc. soln., and that dil soln. may be evaporated to half their vol. without appreciable loss—a rapid volatilization of the acid occurs as the soln. approaches dryness. P. Tschijewsky found that the loss is not proportional to the conc. of the soln. The evaporation on a water-bath of a soln. of *g* grms. of boric acid in 20 grms. of water was attended by the loss of *l* grms. of B_2O_3 per 20 grms. of water:

g . .	1·1296	1·0305	0·9547	0·8874	0·8197	0·0382	0·0201	0·0098
l . .	0·0991	0·0758	0·0673	0·0577	0·0485	0·0181	0·0103	0·0066

F. W. Skirrow distilled sat. soln. of boric acid in contact with the solid phase but did not obtain a distillate of constant composition with unsat. soln.; the conc. of the vapour increases slowly with increasing conc. of the liquid, showing that the acid is not in the same mol. state in the soln. and vapour phases. He believed that in the soln. there is a condition of equilibrium: $2H_3BO_3 \rightleftharpoons 2H_2O + H_2B_2O_4$, and also $4H_3BO_3 \rightleftharpoons 5H_2O + H_2B_4O_7$; and the state of equilibrium between the acid in soln. and in vapour is $H_3BO_{3\,soln.} \rightleftharpoons H_3BO_{3\,vapour}$. The constancy of the "constants" calculated on these assumptions is not altogether satisfactory. J. A. Rose observed an 8·62 per cent. loss of boric acid during the evaporation of ethereal soln. All the boric acid can be volatilized from soln. containing enough methyl or ethyl alcohol.

The **dissociation pressure** at 20° was found by H. Lescœur to be 2 mm., and the **vapour pressure** of boric acid at different temp. to be:

	20°	43·5°	66°	79°	100°	128°
Vap. press. . . .	2	5	16	30	60	242 mm.

He further found at 20° for the vap. press., *p* mm., of a mol of boric oxide, B_2O_3, with *n* mols of H_2O:

n . .	0·01	0·3	0·65	0·98	1·00	1·63	25·0	2·92	2·69
p . .	1·4	2·4	2·2	3·4	7·1	7·2	8·5	9·6	14·5

and at 5°:

n	3·00	3·05	3·20	3·74	3·81
p	1·8	5·8	5·9	6·0	5·95

He inferred that a hydrate higher than H_3BO_3 probably exists at a low temp., but it is not stable at 15°; the vap. press. at 5° is 5·8 mm.; at 10°, 6·8 mm.; and at 15°, 12·1 mm. E. Löwenstein made some observations on this subject. G. Tammann gave 10·2, 26·3, and 56·1 mm. for the **lowering of the vapour pressure** of aq. soln. with respectively 5·25, 13·11, and 27·36 grms. of boric acid per 100 grms. of water, at 100°, and F. W. Skirrow found the vap. press, *p* mm. of aq. soln. with *g* grms. of H_3BO_3 per litre at 92·8°:

g . . .	21·7	23·0	42·8	67·5	80·7	143	152	172
p . . .	579·5	580	578	572	570	566	564	561

The **raising of the boiling point** of aq. soln. of boric acid has been measured by E. Beckmann, W. Landsberger, and L. Kahlenberg, and only varied from 0·49° to 0·51° with soln. containing 2·35 and 36·41 grms. H_3BO_3 per 100 grms. of water. R. Nasini and J. Ageno also found the raising of the b.p. of aq. soln. by boric acid to be in accord with the mol. wt. H_3BO_3 62. S. Arrhenius, and L. Kahlenberg and O. Schreiner measured the **lowering of the freezing point** of aq. soln.; the former *obtained 1·02 for the constant of association*, and the latter found distinct evidence of association as is evident on comparing the first and last of the following:

Conc. of H_3BO_3	0·25	0·167	0·126	mols per litre.
Depression of f.p.	0·489°	0·327°	0·247°	,, ,,
Calculated conc. H_3BO_3	0·27	0·177	0·133	,, ,,

The **partition coefficient** of boric acid between amyl alcohol and water was measured by C. J. J. Fox, P. Muller and F. Auerbach, and found to be nearly constant 3·35 at 25° for soln. of different conc. P. Muller gave 3·37 at 15°; 3·34 at 25°; and 3·31 at 35°. These results indicated that there is no change in the mol. state of boric acid in soln. of different conc. The partition coeff. of boric acid in aq. soln. of sodium chloride and amyl alcohol was measured by P. Muller and R. Abegg; between an aq. soln. of potassium fluoride, and amyl alcohol by C. J. J. Fox; between water, and mixtures of amyl alcohol and carbon disulphide by W. Herz and A. Kurzer; between water and ether, by J. A. Rose; and between amyl alcohol and glycerol, by W. Herz and M. Levy.

According to M. Berthelot,[11] the **heat of formation** of crystalline boric acid is $(B_2O_3, 3H_2O_{liquid})$ 16·8 Cals.; or $(B_2O_3, 3H_2O_{solid})$ 12·6 Cals. A. Ditte found that an eq. of boric acid absorbs 3·187 Cals. in order to make a sat. aq. soln., and if more water is added, only 0·211 Cal. is absorbed. J. Thomsen gave $(H_3BO_3, aq.)$ −5·4 Cals., and M. Berthelot gave 4·8 Cals. for the **heat of solution** of a mol of boric acid in 800 mols of water. This agrees with a large positive temp. coeff. for the solubility. J. Thomsen also found the **heat of neutralization** of one eq. of sodium hydroxide with *n* eq. of boric acid:

n . . .	¼	½	1	1¼	1½	2	4	6
Cals. . .	1·940	6·820	10·010	10·305	10·700	11·100	12·800	13·600

The heat effect which occurs after eq. amounts of acid and alkali have been mixed shows that polyborates are probably formed exothermally. M. Berthelot found that an eq. of boric acid in 4 litres of water with ½ eq. Na_2O per litre=11·56 Cals.; with 1 eq. Na_2O=19·82 Cals.; and with 1½ eq. Na_2O=19·65 Cals. M. Berthelot gave for the heat of neutralization of an eq. of boric acid (70 grms. B_2O_3 in four litres) with one eq. of NH_3 in 2 litres, 8·93 Cals.; with 2 eq. NH_3, 11·55 Cals.; and with 3 eq. NH_3, 12·60 Cals. H. Lunden gave for the heat of neutralization of boric acid with ammonia, 11440−36·8θ cals., at θ°. H. von Steinwehr gave for the **heat of dissociation**, −3·85 Cals. at 18·2°; −4·04 Cals. at 16·4°; and −4·14 Cals. at 13·6°; H. Lunden gave −3·17 Cals. for the heat of dissociation at 15°, and −3·08 Cals. at 25°. J. Thomsen, P. Georgievic, J. Shields, and W. Ostwald found the **avidity** of boric acid for sodium hydroxide to be very small compared with those of other acids.

According to A. des Cloizeaux,[12] the **double refraction** of crystals of boric acid is strongly negative; and the **dispersion** is inappreciable; J. Chaudier found that **elliptical polarization** is produced when 0·3 grm. of boric acid is mixed with 50 c.c. of carbon disulphide, benzene, pseudocumene, turpentine, ether, carbon tetrachloride, chloroform, or petroleum. G. Meslin also studied the polarization of aq. soln. of boric acid. B. Wagner found the **index of refraction** of soln containing 1, 2, 3, and 4 grms. of boric acid in 100 c.c. of soln. to be respectively 1·33396, 1·33464, 1·33532, and 1·33600 at 17·5° for the *D*-line. P. P. Bedson and W. C. Williams found the index of refraction of isotropic fused boric oxide to be 1·4694 for the H_α-line; 1·4637 for the Na-line; and 1·4623 for the H_β-line. J. H. Gladstone and W. Hibbert found that with the H_α-line, solid boric acid has the **molecular refraction** 15·20, and in sat. sol., 14·77. S. Procopiu studied the effect of boric acid on the birefringence of benzene, etc. For the **phosphorescence** of boric acid, *vide* boron trioxide.

E. Bourgoin [13] said that an aq. soln of boric acid is not decomposed by a current, but A. Bartoli and G. Papasogli found that a perceptible decomposition occurs with a current from 6–8 Bunsen's cells. O. Bock found the specific **electrical conductivity** of the soln. at 18° to be:

Per cent. H_3BO_3	0·776	1·92	2·88	3·612
Conductivity	0·022	0·11	0·21	0·31
Temp. coeff.	0·0231	0·0143	0·0119	0·0075

J. Kendall and J. C. Andrews measured the conductivity of boric acid in aq. soln. of hydrochloric and nitric acids. A. B. Bryan measured the conductivity of flames charged with boric acid. J. Walker and W. Cormack gave for the mol. conductivity, μ, the **degree of ionization,** α, and the **ionization constant** of dil. soln. with a mol of the acid in v litres at 18°:

v	11·1	22·2	33·3	44·4
μ	0·0450	0·0636	0·0783	0·0891
Degree ionization, α	$1·37\times10^{-5}$	$1·94\times10^{-5}$	$2·39\times10^{-5}$	$2·72\times10^{-5}$
Ionization constant, K	$1·7\times10^{-9}$	$1·69\times10^{-9}$	$1·71\times10^{-9}$	$1·66\times10^{-9}$

H. Lunden calculated the eq. conductivity of boric acid, assuming the ionization proceeds $H_3BO_3 \rightleftharpoons H' + H_2BO_3'$, at θ°, to be $\lambda_\infty = 18·5 + 0·6471\theta + 0·00328\theta^2$. E. O. Mandala, and H. Menzel have also studied this subject. A. Hantzsch and A. Barth gave $2·3\times10^{-9}$ for the ionization constant of boric acid which thus falls between those of hydrosulphuric and hydrocyanic acids:

	$H(HCO_3)$	H_2S aq.	H_3BO_3	HCy	C_6H_5OH	$H(OH)$
K	$3·04\times10^{-7}$	$0·91\times10^{-9}$	$2·3\times10^{-9}$	$1·3\times10^{-9}$	$1·3\times10^{-10}$	$1·2\times10^{-14}$

G. A. Abbott and W. C. Bray also found the ionization constant $H_3BO_3 \rightleftharpoons H^{\cdot} + H_2BO'_3$, $1·7\times10^{-9}$ at 18°; S. Arrhenius corrected this value to $1·06\times10^{-9}$; H. Menzel gave $5·7\times10^{-10}$ at 18°, and J. Lundberg obtained $6·4\times10^{-10}$ by making an allowance for hydrolysis. Boric acid thus behaves as a weak monobasic acid. The conc. of the H·-ion exceeds 1×10^{-5}, and S. P. L. Sörensen found $6·55\times10^{-5}$, and C. L. A. Schmidt and C. P. Finger, $4·7\times10^{-5}$. S. Arrhenius emphasized the small change in the electrical conductivity of soln. of boric acid with dilution. The splitting of the first of the three H·-ions of boric acid evidently takes place with difficulty; and the tertiary salts of boric acid are not formed in aq. soln., for the acid is also considerably hydrolyzed. For soln. of boric acid F. Auerbach, W. M. Clark and H. A. Lubs, E. B. R. Prideaux and co-workers, S. Palitzsch, S. P. L. Sörensen, and C. L. A. Schmidt and C. P. Finger found that the ionization constant is increased by decreasing the conc. of the soln., and for very dil. soln. is not far from $k=1·7\times10^{-9}$; and that the addition of a neutral salt increases the value of k. J. Walker calculated the **degree of hydrolysis** to be 0·84 per cent. with 0·1*N*-soln. of borax, to be 0·3 per cent., and J. Shields found 0·5 per cent. J. Lundberg calculated the OH′-conc. of borate soln. from the velocity of saponification of esters and found the hydrolysis constant $K=[OH'][HBO_2]/[BO_2']$, to be $1·9\times10^{-5}$ at 18°; H. Menzel gave $1·12\times10^{-5}$ at 18°. G. Magnanini found for four litres of soln. containing 1, 0·5, and 0·1 mols of mannite, $C_6H_8(OH)_6$, and one mol of boric acid the mol. conductivity, 100μ, falls from 120 to 65·0 to 16·4; and with four litres of a soln. containing a mol of mannite and 1, 0·5, and 0·1 mols of boric acid, the mol. conductivity, 100μ, falls from 118 to 93·5 to 43·4. He infers *that the conductivity is approximately proportional to the conc. of the mannitol, and to the cube root of the conc. of the boric acid*; and this agrees with the mass *law on the assumption that three mols of mannitol and one mol of boric acid form a complex ion.* He also studied the action of glycerol and erythritol. H. Lunden found for the **transport number** of the ion H_2BO_3' is 29·0 at 15°; 36·8 at 25°; and and 49·7 at 40°. C. L. A. Schmidt and C. P. Finger studied the potential difference of the **hydrogen electrode** in a soln. of boric acid.

G. Gore[14] found that a copper plate at 100° is electropositive towards a cold plate in a soln. of boric acid. G. Meslin found the **magnetic susceptibility** of boric acid to be $-0{\cdot}60\times10^{-6}$ mass units.

The solubility of orthoboric acid.—The solubility of boric acid in *water* has been measured by R. Brandes and E. Firnhaber,[15] and by A. Ditte. The latter represented the amount, S, in grams of boric acid dissolved in a litre of water at $\theta°$, by $S=19{\cdot}4+0{\cdot}63636\theta+0{\cdot}016608\theta^2-0{\cdot}00001604\theta^3$, but his results are undoubtedly too low. R. Nasini and J. Ageno gave for the percentage solubility :

	0°	10	20°	40°	60	80°	100°	120°
H_3BO_3 . .	2·59	3·45	4·8	8·02	12·90	19·11	28·7	52·4

They gave −0·76° for the eutectic temp. with a soln. containing 2·27 per cent. of boric acid; F. Guthrie gave −0·7° for the eutectic temp. W. Herz and F. Auerbach also obtained some isolated data for the solubility of boric acid in water; and W. Herz and M. Knoch found the normality of aq. soln. sat. at 13°, 20°, and 25° to be respectively 0·620, 0·7915, and 0·8999.

R. Abegg, C. J. J. Fox, and W. Herz found that water at 26° dissolves 0·80 mol of boric acid, and with 3·21 and 2·80N-soln. of *hydrofluoric acid*, 0·75 and 0·96 mol of boric acid are dissolved, so that the solubility of boric acid is depressed by hydrofluoric acid. W. Herz represented the solubility of boric acid in terms of normal soln. at 26°. Without acid, the soln. of boric acid is 0·907N-H_3BO_3, and with *hydrochloric acid* :

N-HCl . .	0·130	0·260	0·390	1·30	2·16	6·0	7·08	9·51
N-H_3BO_3 .	0·895	0·870	0·842	0·645	0·542	0·338	0·327	0·338

showing that the solubility decreases with increasing proportions of acid and finally attains a constant value with about 5N-HCl. J. Kendall and J. C. Andrews also measured the solubility of boric acid in hydrochloric acid. A. Ditte said that boric acid is more easily soluble in dil. hydrochloric acid than in water; and all three agree that there is no sign of a combination of the two acids. W. Herz's results with *sulphuric acid* are, at 26° :

N-H_2SO_4	0·548	2·74	5·48	8·75
N-H_3BO_3	0·746	0·518	0·312	0·092

L. Gmelin, H. Schiff, and G. Merz found that with conc. sulphuric acid, a colourless viscid mass is produced from which water precipitates boric acid—*vide* boron sulphate. With *nitric acid*, W. Herz found at 26° :

N-HNO_3 . .	0·241	1·206	1·607	2·411	5·96	7·38
N-H_3BO_3 . .	0·818	0·676	0·593	0·567	0·268	0·238

showing a steady fall in the solubility as the conc. of the nitric acid increases. With 0·570N-, 2·85N-, and 5·70N- *acetic acid*, W. Herz found sat. soln. contained respectively 0·887N-, 0·538N-, and 0·268N-boric acid, at 26°. P. Schützenberger described a compound of acetic and boric acids. According to A. Holt, orthoboric acid is readily soluble in hot glacial acetic acid, from which it separates out unchanged on cooling. The pyro-acid and boric anhydride are insoluble, whilst metaboric acid dissolves to a very slight extent, the soln. depositing the ortho-acid on cooling. M. P. Dukelsky studied the ternary system, $H_3BO_3—H_2O—(CH_3CO)_2O$. W. Herz found the solubility of boric acid and *oxalic acid* at 25° in grams per 100 c.c. of sat. soln. to be:

$H_2C_2O_4$	2·26	5·36	12·39	11·27	10·84	10·77	10·63
H_3BO_3	6·17	6·70	7·44	3·43	0·97	0·55	0
Solid phase	Boric acid.			Oxalic acid.			

W. Herz also gave with *tartaric acid* at 25° (grams per 100 c.c. of sat. soln.):

	d-tartaric acid.			*l*-tartaric acid.		
$H_6C_4O_6$	0	11·25	15·00	9·43	18·90	37
H_3BO_3	5·59	6·20	7·48	6·11	6·48	7·23

showing that the solubility increases with increasing proportions of acid. G. Magnanini, A. F. W. Duve, G. Baudran, and H. Grossmann and L. Wieneke observed the formation of complexes with tartaric acid. W. Herz gave for soln. with 2·321, 18·77, 36·33 molar per cent. of *lactic acid* at 25°. respectively 6·64, 11·53, and 12·90 grms. of boric acid per 100 c.c. of sat. soln. at 25°, and G. Magnanini observed the formation of complexes with these two acids. P. Muller and R. Abegg also measured the solubility of boric acid in lactic acid. A compound of boric acid with *benzoic acid* was described by A. Michaelis and E. Richter; with *citric acid*, by A. Scheibe; and with *salicylic acid* by E. Jahns.

P. Bogdan measured the solubility of boric acid in aq. soln. of *sodium chloride* and *potassium chloride* at 25°, and W. Herz, in aq. soln. of *lithium chloride* and *rubidium chloride* at 25°. The results interpolated by A. Seidell, so as to show the number of grams *g* of the chloride per 100 c.c. of sat. soln., with the number of grams of boric acid dissolved per 100 c.c. of sat. soln., at 25°, when the solubility in water alone ($g=0$) is 5·59 are:

g	2	4	6	8	10	15	20	30
HCl	4·92	4·36	3·88	3·50	3·15			
LiCl	5·20	4·85	4·45	4·07	3·75	3·00		
NaCl	5·40	5·30	5·20	5·15	5·10	5·07		
KCl	5·67	5·75	5·85	5·90	6·00	6·25	6·50	
RbCl	5·60	5·62	5·67	5·72	5·77	5·90	6·10	6·55

P. Bogdan also measured the solubility of boric acid in soln. of *potassium and sodium nitrates*, and in *potassium and sodium sulphates*, and, expressing the results as above, found 5·75 with water alone, $g=0$:

g	10	20	40	60	80
NaCl	5·75	5·74	5·72	5·72	5·71
KCl	5·80	5·86	5·98	6·12	6·29
$NaNO_3$	5·78	5·81	5·87	5·95	6·02
KNO_3	5·81	5·88	6·04	6·20	6·37
Na_2SO_4	5·88	6·00	6·33	6·70	7·10
K_2SO_4	5·92	6·10	6·50	6·92	7·40

P. Bogdan added that the raising of the solubility is the more marked the weaker the acid of the added salt, and is probably to be ascribed to chemical action. F. Auerbach gave for the solubility of boric acid in soln. of *borax*, in mols per litre at 25°:

Na	0	0·05	0·075	0·10	0·15	0·20
Excess acid over B : Na	0·885	1·075	1·155	1·25	1·37	1·51
Excess acid over 2B : Na	0·885	1·025	1·08	1·15	1·22	1·31
Total conc. B	0·885	1·125	1·23	1·35	1·52	1·71
Combined B	0	0·240	0·345	0·465	0·635	0·825
Ratio Na to combined B	—	4·8	4·6	4·65	4·2	4·1
B in polyborates	—	0·236	0·340	0·458	0·624	0·811

Borax thus augments the solubility of boric acid. M. Puaux obtained soln. containing boric acid eq. to a hexaborate, by adding a little calcined *magnesium oxide* to the boiling soln., and then more boric acid. The magnesia keeps the soln. alkaline, and this enables more boric acid to dissolve. For a 10 per cent. soln. of boric acid—sp. gr. 1·044–1·4 grms. of magnesia are needed; and for a 20 per cent. soln.—sp. gr. 1·088–3·5 grms. of magnesia are required. T. W. B. Welsh and H. J. Broderson found 100 grms. of anhydrous *hydrazine* dissolved 55 grms. of boric acid at room temp. P. Bogdan found that at 25° soln. containing 0, 20, 60 grms. of *urea* per 100 grms. of water dissolved respectively 5·75, 5·93, and 6·31 grms. of boric acid per 100 grms of water.

P. Müller and R. Abegg measured the solubilities of boric acid in aq. soln. of *methyl, ethyl, propyl, iso-butyl,* and *iso-amyl alcohols.* Expressing the amount of alcohol in per cent. by weight, and the amount of boric acid in grams per 100 c.c. of sat. soln., at 25°, they obtained:

CH_3OH	19	41·5	50	58	66	100
H_3BO_3	5·55	6·27	6·81	7·20	8·10	17·99
C_2H_5OH	20·2	42·3	76·3	91·1	95	100
H_3BO_3	5·14	4·96	4·34	5·54	6·85	9·47
C_3H_7OH	50·83	79·41	95·5	100	—	—
H_3BO_3	3·99	2·83	3·58	5·96	—	—
C_4H_9OH	0·70	2·18	71·4	77·1	85·6	100
H_3BO_3	5·48	5·32	2·00	2·15	2·61	4·30
$C_5H_{11}OH$	0·148	0·525	67·26	75·54	83·40	100
H_3BO_3	5·48	5·46	1·60	1·69	1·98	3·54

The results are plotted in Fig. 11. The sp. gr. of the soln. were also measured. A. Seidell has also measured the solubilities of soln. in ethyl alcohol at 10° and 25°; and P. Bogdan, the solubility in propyl alcohol. The diminishing solvent power of alcohol for boric acid as the amount of water increases is attributed to the breaking down of a compound with alcohol and boric acid; and the variation in the different alcohols is taken to indicate that the affinity of boric acid for alcohol with increasing carbon content, decreases more rapidly than the affinity of boric acid for water. The limited miscibility of the higher alcohols in water accounts for the dotted lines in the curves.

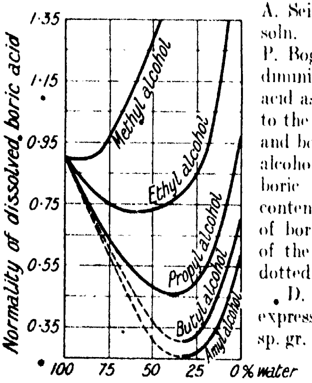

FIG. 11.—Solubility of Boric Acid in Mixtures of Alcohol and Water at 25°.

D. Hooper measured the solubility of boric acid expressed in grams per 100 grms. of *glycerol* of sp. gr. 1·260 at 15·5°, and found:

	0°	10°	20°	40°	60°	80°	109°
H_3BO_3	20	24	28	38	50	61	72

W. Herz and M. Knoch found that at 25°, 100 grms. of a solvent containing *n* per cent. of glycerol, dissolved the following percentage amounts of boric acid:

Glycerol soln., *n*	0	7·15	31·55	40·95	48·7	69·2	100
H_3BO_3	5·50	5·38	5·29	5·41	5·64	7·32	19·02

P. Müller and R. Abegg, and A. M. Ossendowsky also measured the solubility of boric acid in glycerol. P. Müller and R. Abegg measured the solubility of boric acid in soln. of dulcitol and of mannitol and gave for soln. containing 0·065, 0·130, and 0·260 molar per cent. of *dulcitol*, $C_6H_8(OH)_6$, the respective solubilities 5·50, 5·63, and 5·81 grms. of boric acid per 100 c.c. of sat. soln. at 25°. Expressing the results in grams per 100 c.c. of sat. soln., F. Ageno and E. Valla found for *mannitol*, $C_6H_8(OH)_6$, at 25°:

Mannitol	0	1·82	9·11	14·57	32·43	27·97	24·65	19·58
H_3BO_3	5·50	5·90	6·64	7·27	9·43	7·71	4·92	0
Solid phase	H_3BO_3					$C_6H_8(OH)_6$		

G. Magnanini's observations are discussed in connection with the electrical conductivity of aq. soln. of mannitol and boric acid.

H. Schiff, and H. Rose said dried *ether* dissolves only traces of boric acid, and J. A. Rose showed that the solubility increases with increasing proportions of water. Thus, 100 grms. of dried ether dissolve 0·00775 grm. of boric acid, and 100 grms. of ether sat. with water dissolve 0·2391 grm. He also measured the partition coeff. as indicated above, and found for $H_2O : (C_2H_5)_2O = 1 : 45·37$ at 27°, 1 : 44·62 at 17°. D. H. Wester and A. Bruins found 100 grms. of *dichloroethylene*, at 15°, dissolved 0·006 grm. of boric acid; and 100 grms. of *trichloroethylene*, 0·016 grm. P. Bogdan measured the solubility of boric acid in *acetone* at 20°, and W. Herz and M. Knoch, at 20°. The latter give, per 100 c.c. of solvent:

Acetone	0	20	40	60	80	100
H_3BO_3	4·91	5·07	5·13	4·74	3·41	0·50

J. Timmermans found that with a 64 per cent. soln. of *phenol* the molar conc. rose from 1·291 to 1·62. H. Rose found boric acid dissolves in many *essential oils*.

The relation of boric acid to indicators.—According to M. Faraday,[16] and M. Desfosses, *turmeric* paper dipped in a soln. of boric acid is quickly coloured brownish-red, and when the paper is dried, the effect resembles that produced by a weak alkali. The original colour is restored by washing the paper. The mineral acids and oxalic acid produce a bright red with the browned paper, and alkalies turn the brown paper into various shades of yellowish-red, purple, and blue. If the browned paper be heated, the turmeric yellow is almost restored. The effect produced by aq. ammonia or hydrochloric acid on the browned paper is lost by volatilization. Boric acid in all states of dilution reddens turmeric paper, but with very dil. soln., it requires a few minutes to produce the effect. Soln. once made acid, redden litmus and turmeric, however much they be diluted, so that the acidified soln. does not become alkaline when diluted. A cold sat. soln. of boric acid colours blue *litmus* wine-red, and, according to F. J. Malaguti, the colour becomes bright when the soln. is heated. D. Klein showed that a soln. of boric acid which is so diluted that it does not react to litmus, develops a strong acid reaction if glycerol, erythritol, mannitol, or galactose is added; blue litmus, he added, is reddened by boric acid in the presence of mannitol if but 0·00005th of boric acid is present. These carbohydrates accentuate the acidity of boric acid. Quercitol does not show the reaction. The reaction has also been discussed by J. A. Rose, R. T. Thomson, etc. F. A. Fluckiger and R. T. Thomson noted that *phenolphthalein*, reddened by the addition of an alkali, is decolorized by boric acid. In the titration of borax with 0·5*N*-hydrochloric acid, and *p*-nitrophenol as indicator, the soln. reacts acid only when all the soda has been neutralized; *p*-nitrophenol is indifferent to boric acid. The boric acid can then be titrated in the same liquid with the same standard alkali by using phenolphthalein as indicator, in the presence of glycerol or mannitol. J. L. Gay Lussac used litmus as indicator in titrating boric acid; F. Parmentier, and A. Joly, *helianthin*; R. Engel, *Porrier's soluble blue*; A. Guyard, *hæmatoxylin*; V. de Luynes, *orceine*; C. Schwarz, *congo red*; R. T. Thomson, *lacmoid*; L. Barthe, tincture of *rose leaves*; L. Robin, tincture of *mimosa blossoms*; H. N. Morse and W. M. Burton, and A. Joly, *tropæolin*; R. T. Thomson, and A. Joly, *methyl orange*; R. T. Thomson, *phenolacetolin*.

When two electrodes of the same metal are placed in two soln. in electrical contact containing the ion of the metal in different conc., C_1 and C_2 respectively, the difference of potential, E, is given fairly closely by $E=0{\cdot}000198T/(\log_{10} C_1/C_2)/n$, when n is the valency of the ions of the metal in soln., and T is the absolute temp. The principle can be employed to determine, say C_2, the conc. of the H·-ion in soln., for, at 18°, with the normal hydrogen electrode $C_1=1$, and $n=1$, the measurement of E enables C_2 to be calculated from $E=0{\cdot}058 \log_{10} (1/C_2)$. W. Böttger[17] first used this principle for the electrometric titration of acids and bases. According to J. Stieglitz, indicators can be regarded as acids and bases which take part in the equilibrium of the system in virtue of the H·-ions or OH′-ions, for, even if the colour changes are directly dependent on tautomeric structural changes, the change of colour is a function of the H·-ions, and, as A. A. Noyes has emphasized, if the ionization constant of the indicator be known, the conc. of the H·-ion at which the colour change occurs can be computed. H. Friedenthal, W. Salessky, B. Fels, S. P. L. Sörensen, E. Salm, etc., have determined the conc. of the H·-ion at which the colour change occurs, and the following is a selection from the results of the last named :

Representing the conc. of the H·-ion in terms of the nearest power of 10, *cochineal* is yellow for 10^{-4}, yellowish-pink for 10^{-5}, and lilac for 10^{-6}; *Congo red* is blue for 10^{-3}; violet for 10^{-4}; reddish-violet for 10^{-5}; orange for 10^{-6}; and orange-red for 10^{-7}; *helianthin* is yellow with 10^{-13}, and lilac with 10^{-14}; *litmus* is red for 10^{-5}; reddish-violet for 10^{-6}; violet for 10^{-7}; and blue for 10^{-8}; *methyl red* is red for 10^{-3}; pinkish-yellow for 10^{-5}; and yellow for 10^{-6}; *methyl orange* is rose-red for 10^{-1}; orange for 10^{-4}; pinkish-yellow for 10^{-5}; and yellow for 10^{-6}; *p-nitrophenol* is colourless for 10^{-5}; light green for 10^{-6}; and yellow for 10^{-7}; *phenacetolin* is yellow for 10^{-4}; brownish-red for 10^{-5}; rose-red for 10^{-6}; violet-red for 10^{-11}; and colourless for 10^{-12}; *phenolphthalein* is colourless for 10^{-8}; and red for 10^{-9}; while *tropæolin* 00 is cherry-red for 10^{-1}; flesh-colour for 10^{-2}; and yellow for 10^{-3}.

In Fig. 12, the e.m.f. expressed in terms of the computed conc. of the H·-ion is plotted during the addition of standard alkali to a soln. of boric acid and of hydrochloric acid. The greater jump in the range with hydrochloric acid than with boric acid shows that in the former case a slight addition of alkali suffices to change the conc. of the H·-ion through a range from 10^{-2} to 10^{-10}, whereas with boric acid alone, the range is very narrow on each side of 10^{-11}. Otherwise expressed, in titrating hydrochloric acid with alkali, the acidity of the soln., *i.e.* the conc. of the H·-ion changes through a range great enough to include the colour changes characteristic of most indicators, but with the titration of hydrochloric acid with methyl orange as indicator a very slight addition of alkali at the end-point is sufficient to change the acidity, that is, the conc. of the H·-ion through a range great enough to include all the colour changes of the indicator in question. With boric acid, however, the rapid change in acidity at about 10^{-9}, throws out methyl orange changing between 10^{-4} and 10^{-5}, long before the eq. amount of base has been added; nor does phenolphthalein changing at 10^{-8} give a satisfactory end-point. An indicator changing colour near the middle of the jump in the curve will in general give the sharpest end-point. The conc. of the H·-ion at which an indicator changes colour may be different from E. Salm's value, but if 1, 3, 5, 7, 9 grms. of mannitol be

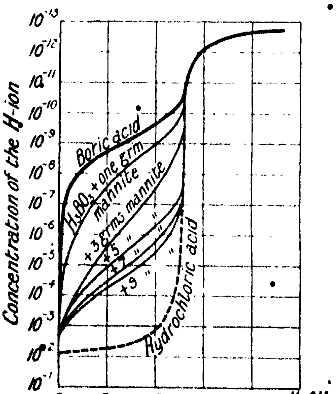

FIG. 12. Electrometric Titration of Hydrochloric Acid, and of Boric Acid (with and without Mannite) by Standard Sodium Hydroxide.

progressively added, there is a proportionate increase in the $H^{\cdot}$-ion conc. of the soln., until the strength of the boric acid becomes great enough to permit its titration with phenolphthalein. An indicator changing at 10^{-11} would permit the titration of boric acid without the addition of mannitol. The subject has also been studied by E. Rimbach and P. Ley, and R. Dubrisay.

Some chemical properties of boric acid.—H. Schiff and R. Sestini[18] found that **iodine** has no action on boric acid. The action of **hydrochloric acid** is indicated in dealing with the solubility; similar remarks apply to aq. soln. of the **alkali chlorides.** H. Baubigny and P. Rivals found boric acid decomposed hot soln. of chlorides, or **bromides** provided the soln. is sat. If **hydrogen bromide** be passed into an alcoholic soln. of boric acid, J. Nicklès found that boron bromide and a complex of that salt with alcohol are formed. R. Höpke investigated the influence of boric acid on the reaction between **iodic acid** and sulphur dioxide. H. N. Warren found that if boric acid be added to molten sodium chloride, a layer of fused borax appears under the molten sodium chloride; and M. G. Levi and S. Castellani proposed the reaction for converting boric acid into borax. G. Ubaldini found that iodine separated when an **alkali iodide** is triturated with boric acid provided air has free access or the soln. be hot. H. Baubigny and P. Rivals also observed that boric acid decomposes a cold soln. of **potassium iodide** with the separation of hydrogen iodide, but P. Georgievic said that boric acid does not liberate iodine from a mixture of potassium iodide with potassium iodate, or nitrite.

The action of **sulphuric acid,** and of **potassium and sodium sulphates,** has been discussed in connection with the solubility of boric acid; and the action of sulphuric acid, and **sulphur trioxide,** is treated in connection with boron sulphate. Boric acid is so weak an acid that it is readily expelled from many of its combinations, and partially so even by hydrosulphuric and carbonic acid. A boiling conc. soln. decomposes soluble **sulphides,** as well as manganese sulphide. In a dry way, at high temp., boric acid will decompose the salts of all more volatile acids. H. Schulze studied the action of boric acid on colloidal **antimony sulphide.** A. Étard found boric acid has no action on a soln. of **ammonium magnesium sulphate,** $(NH_4)_2SO_4.MgSO_4.6H_2O$, but if some **hydrogen peroxide** be present a white precipitate is formed. The action of various organic compounds on boric acid has been discussed in connection with the solubility of boric acid. D. Klein studied the action of **polyhydric alcohols** on boric acid. E. Tiede and E. Birnbräuer said that boron oxide forms a carbide when it is heated with **carbon.** As indicated above, **carbonic acid** will displace boric acid from the borates, but a boiling conc. soln. will decompose the **carbonates.** F. Ageno studied the partition of sodium oxide between boric and carbonic acids. When a is the total conc. of the sodium oxide, x that required by the combined carbonic acid, C the total conc. of the carbonic acid, then, with soln. sat. with boric acid—0·90 mol per litre, then $K=0{\cdot}90x/(a-x)(C-x)$; but K, at 25°, varies from 2·37 to 0·827 as the conc. of the sodium oxide is increased. The deviations from constancy are said to be due to variations in the solubility of carbon dioxide in the presence of borates and hydrocarbonates; and to the formation of polyborates with increasing conc. of the sodium oxide. P. Georgievic found boric acid has no visible action on soln. of the **alkali carbonates or bicarbonates,** but, added C. Jehn, effervescence occurs if glycerol, honey, or one of the polyhydric alcohols be present; neither quercitol nor glycogen has any action. L. Reed found that by mixing boric acid and **calcium carbonate** (1 : 20) with water to form a slip, a hard cement-like mass is obtained in a few days—the setting is retarded by mercuric iodide, lead chromate, and ultramarine. F. de Lalande and M. Prud'homme showed that a mixture of boric oxide and **sodium chloride** is decomposed in a stream of dry air or oxygen at a red heat with the evolution of chlorine.

The effect of boric acid on the setting of hemihydrated **calcium sulphate** is treated in connection with plaster of Paris. H. Rose found if an aq. soln. of boric acid and **ammonium chloride** is evaporated to dryness, and the mixture calcined with the exclusion of air, some boron nitride is formed; **ammonium nitrite** furnishes no nitride under similar conditions. The effect of **potassium and sodium nitrates** is discussed in connection with the solubility of boric acid. It has been suggested that boric acid can be used in the preparation of nitric acid from Chili saltpetre, and so obtain borax as a by-product. F. Auerbach found that a complicated condition of equilibrium occurs with a mixture of boric and **arsenious acids** competing for sodium oxide insufficient for complete neutralization. Both acids form complex compounds.

G. F. Jaubert found **sodium dioxide** converts boric acid into a perborate (*q.v.*). A. Étard prepared *barium diborate*, $BaB_2O_5.3H_2O$, by the action of **barium dioxide** on boric acid. By the action of boric acid on a mixture of **calcium oxide** and boric oxide, C. Bigot and J. Schreiter obtained what they regarded as *dicalcium diborate*, $Ca_2B_2O_5$, from which he made the *tetrasodium diborate* by treating with sodium sulphate. L. de Koningh ignited a dried mixture of boric acid and an excess of **ammonium zincate,** and obtained zinc oxide free from boric oxide. T. Bergman in his arguments in favour of regarding *sal sedativum* as an acid stated: "The acid of borax attacks **metals** with difficulty." C. Tissier, and H. Rose found **calcium hydroxide** dissolves in a boiling conc. soln. of boric acid; **calcium and barium carbonates** do not dissolve; hydrated **magnesium carbonate** dissolves quickly; the anhydrous carbonate does not dissolve; and calcined **magnesium oxide** slowly; **ferrous hydroxide** dissolves, and if air be present, ferric hydroxide is precipitated; **manganous hydroxide** dissolves and remains in soln. on exposure to air; and **zinc oxide, aluminium hydroxide or oxide** and **ferric oxide** dissolve in the soln. P. Georgievic found that the brownish-red colour of **ferric chloride** in acetate soln., or the violet colour of ferric chloride in phenol soln. is discharged by boric acid. M. Berthelot said that boric acid converts **potassium chromate** to the dichromate, but P. Sabatier found very little action. When boric acid is heated with **ammonium fluosilicate,** F. Stolba found ammonium borofluoride is formed. L. Kahlenberg and W. J. Trautman did not succeed in reducing boric oxide by **silicon.** The tendency of boric oxide or acid to form complexes is well illustrated by its compounds with inorganic acids as well as by the corresponding salts: *e.g.*, borophosphates, boroarsenites, borotungstates, boromolybdates, and borovanadates *q.v.*

§ 9. The Alkali and Ammonium Borates

A. C. Reischle[1] prepared **lithium orthodihydroborate,** $LiH_2BO_3.7H_2O$, by mixing aq. soln. of boric acid, and of lithium oxide made by igniting the nitrate in hydrogen, and evaporating to crystallization in a vacuum. It forms thin, hexagonal tables, which are described in detail in the paper, together with the method of analysis. The water of crystallization is lost at 110°, the remainder at 160°. H. le Chatelier prepared triclinic plates of anhydrous **lithium metaborates or diborate,** $Li_2O.B_2O_3$, or $LiBO_2$, by melting boric oxide with the calculated quantity of lithium carbonate; and A. C. Reischle by adding an alcoholic soln. of boric acid to a soln. of lithium metal in absolute alcohol. The white crystals obtained by the latter process contain alcohol of crystallization which is not removed in vacuo, but is expelled by gentle heat. H. S. van Klooster gave 813° for the m.p. of lithium metaborate. G. Tammann found that the heat of soln. of the metaborate glass in *N*-HCl is 259 cals. per gram, and of the crystals, 203 cals. per gram. Hence the heat of crystallization is 56 cals. per gram.

C. L. Bloxam found that at a bright red heat, a mol of boric acid expels 2·5 mols of carbon dioxide from 3 to 5 mols of lithium carbonate. G. Ribaud studied the f.p. curves of the binary system $Li_2O-B_2O_3$ and found a maximum corresponding with **lithium metaborate,** $LiBO_2$, fusing at 840°, and one corresponding with **lithium tetraborate,** $Li_2O.2B_2O_3$, fusing at 900°. By applying the phase rule to the lithium borates in aq. soln., M. Dukelsky studied the ternary system: $Li_2O-B_2O_3-H_2O$, at 30°. The region of stability of the solid phase $LiOH.H_2O$ is represented in Fig. 13 by the area *abLiOH.H₂O*; the phase $LiO_2.B_2O_3.16H_2O$ by the area *bcM*; the region of stability of the phase $Li_2O.2B_2O_3.nH_2O$ was not clearly established; the phase $Li_2O.B_2O_3.10H_2O$, by the area *deP*; and of boric acid, $B(OH)_3$, by the area *feB*.

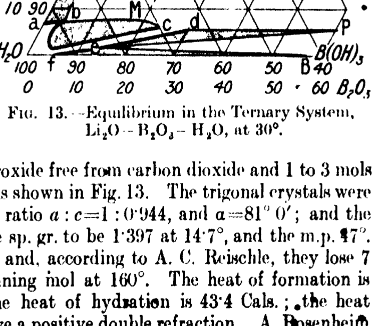

Fig. 13.—Equilibrium in the Ternary System, $Li_2O-B_2O_3-H_2O$, at 30°.

H. le Chatelier prepared **octohydrated lithium metaborate,** $Li_2O.B_2O_3.16H_2O$, or $LiBO_2.8H_2O$, by crystallization of a soln. of the cake obtained by melting 2 mols of lithium hydroxide with one of boric oxide, or by crystallization in vacuo of an aq. soln. of lithium hydroxide free from carbon dioxide and 1 to 3 mols of boric acid. The region of stability is shown in Fig. 13. The trigonal crystals were found by P. Termier to have the axial ratio $a:c=1:0·944$, and $\alpha=81° 0'$; and the sp. gr. 1·38; H. le Chatelier found the sp. gr. to be 1·397 at 14·7°, and the m.p. 47°. The crystals slowly effloresce in air; and, according to A. C. Reischle, they lose 7 mols of water at 114°, and the remaining mol at 160°. The heat of formation is $B_2O_{3soln.}+2LiOH_{soln.}=18·6$ Cals.; the heat of hydration is 43·4 Cals.; the heat of soln., −28·4 Cals. The crystals have a positive double refraction. A. Rosenheim and W. Reglin found that the solubility coeff. is positive, and the depression of the f.p. of soln. is normal. They gave for the solubility of the salt (grams per 100 grms. of soln.) 0·89 at 0°; 3·42 at 25·6°; 9·42 at 38·8°; and 14·7 at 44·8°; while H. le Chatelier gave 0·70 at 0°; 1·91 at 15°; 3·7 at 27·5°; 5·28 at 31·5°; 9·1 at 37·5°; 14·3 at 43°; and 20·0 at 45°. The last number is considered to be too high. F. M. Jäger found for the anhydrous salt the surface tension in ergs per sq. cm., 261·8 at 879·2°, and 192·4 at 1520°. The salt melts 845°. G. Ribaud gave 840° for the m.p. F. M. Jäger found the salt begins to give off vapour at about 1200°, and that the vapour is alkaline. The volatilization of lithium oxide is fairly rapid at 1300°.

In 1818, J. A. Arfvedson[2] boiled an aq. soln. of boric acid with an excess of lithium carbonate, and when the evolution of carbon dioxide had ceased, he filtered the clear liquid from the excess of carbonate, and obtained on evaporation a syrupy liquid which when rubbed up with alcohol a number of times, furnished a white crystalline powder. C. G. Gmelin obtained this salt in the form of a transparent green mass; and M. Dukelsky could obtain only a colloidal form from aq. soln. F. Filsinger's analysis agrees with **pentahydrated lithium tetraborate,** $Li_2O.2B_2O_3.5H_2O$, or $Li_2B_4O_7.5H_2O$. M. Dukelsky's study showed that such a borate is formed in aq. soln., but he did not establish its composition, nor locate the course of the curve between *c* and *d*, Fig. 13. J. A. Arfvedson's crystals were said to have an alkaline taste and reaction; and to be soluble in water F. Filsinger said that two-fifths of the water are lost at 200°; to swell up and lose their water of crystallization when heated, and ultimately to fuse to a transparent glass. F. Filsinger obtained what he regarded as **hexahydrated lithium hexaborate,** $LiB_3O_5.3H_2O$, or $Li_2O.3B_2O_3.6H_2O$, by crystallization from a soln. prepared like the tetraborate, and mixed with an eq. amount of boric acid. The salt was found to behave like the preceding salt when heated; to be readily soluble in water, and insoluble in alcohol and ether. M. Dukelsky did not find the salt in his exploration at 30°, but he obtained **decahydrated lithium decaborate,** $LiB_5O_8.5H_2O$, or $Li_2O.5B_2O_3.10H_2O$, stable in the region *deP*, Fig. 13. H. le Chatelier obtained insoluble prismatic crystals of what he regarded as **lithium octoborate,** $Li_2O.4B_2O_3.(nH_2O)$, or $Li_2B_8O_{13}.(nH_2O)$, by extracting with water the cold cake obtained by the fusion of a mol of lithium carbonate, with six mols of boric oxide. M. Dukelsky did not find this salt in his study of the stable phases in aq. soln. at 30°. A. C. Reischle suggested that some of these borates are mixtures with carbonate. J. A. Arfvedson, C. L. Bloxam, E. Mallard, and H. Rose measured the amount of gas expelled from sodium carbonate when fused with a mol of boric acid, from which it appears that at a dull red heat, a mol of boric oxide drives off a mol of carbon dioxide from 1·2 to 3·1 mols of sodium carbonate; and at a bright red heat, 1·5 to 2·3 mols of carbon dioxide from 1·5 to 5·6 mols of sodium carbonate. C. L. Bloxam also measured the amount of water expelled when sodium hydroxide is fused with boric acid, and found that a mol of boric oxide can displace 3 mols of water from the fused hydroxide. The results have been cited as evidence of the formation of the **basic sodium borates**: $3Na_2O.2B_2O_3$ was given by J. A. Arfvedson, and H. Rose; $5Na_2O.3B_2O_3$, by C. L. Bloxam; and $3Na_2O.B_2O_3$, by C. L. Bloxam and E. Mallard.

I. F. Ponomareff studied the binary system with borax and boric oxide, and obtained evidence of the formation of sodium hexaborate, $Na_2O.3B_2O_3$, or $Na_2B_6O_{10}$, m.p. 694°; and of sodium octoborate, $Na_2O.4B_2O_3$, or $Na_2B_8O_{13}$, m.p. 783°. These salts form mixed crystals with each other and with boric oxide. M. Dukelsky studied the eq. conditions in the ternary system: $Na_2O-B_2O_3-H_2O$, at 30°, and his results are summarized in Fig. 15. The line *ab* represents the solid phase $NaOH.H_2O$ in eq. with the soln.; the line *bc*, with the metastable phase corresponding with *cm*, represents the solid phase $Na_2O.B_2O_3.4H_2O$; the line *cd*, the phase $Na_2O.B_2O_3.8H_2O$; the line *de*, the phase $Na_2O.2B_2O_3.10H_2O$; the line *ef*, the phase $Na_2O.5B_2O_3.10H_2O$; and the line *fg*, the phase $B(OH)_3$.

U. Sborgi and F. Mecacci also investigated the same ternary system at 60°, and obtained in addition, the solid phases **monohydrated tetrasodium diborate,** $2Na_2O.B_2O_3.H_2O$, or $Na_4B_2O_5.H_2O$, corresponding with the region *bMc*, Fig. 14; $Na_2O.B_2O_3.H_2O$, with the region *cOd* and extending as an unstable phase along the dotted curve *dm*; the pentahydrate $Na_2O.2B_2O_3.5H_2O$ also appears in the region *ePf*; the phases corresponding with those observed by M. Dukelsky at 30°, are $Na_2O.B_2O_3.4H_2O$—*dDe*; $Na_2O.5B_2O_3.10H_2O$—*fOg*; $NaOH.H_2O$—*Nab*; and $B(OH)_3$—*gBh*. The phases $Na_2O.B_2O_3.8H_2O$ and $Na_2O.2B_2O_5.10H_2O$ do not appear at 60°.

J. J. Berzelius, and G. M. Wunder made anhydrous **sodium metaborate or diborate,** $Na_2O.B_2O_3$, or $NaBO_2$, by heating a mixture of equi-molar parts of sodium carbonate and borax. According to A. Stromeyer, by mixing alcoholic soln. of sodium hydroxide and boric acid, crystals of borax and a viscid liquid are produced; the latter furnishes crystals of anhydrous sodium borate after standing some time. M. Aschkenasy prepared the metaborate by adding powdered crystalline borax to a conc. soln. of sodium hydroxide and drying the solid in vacuo at a moderate temp. S. Motylewsky found the drop-weight of the molten salt to be 229, when that of water at 0° is 100 mgrms. F. M. Jäger, and R. Lorenz and W. Herz gave 112·3 for the surface tension of sodium metaborate in ergs per sq. cm. at its b.p., and 201·1 at its m.p. H. S. van Klooster, and F. M. Jäger gave 966° for the m.p. of sodium metaborate. The latter found vaporization begins at 1230°, and is rapid at 1350°. R. Benedikt prepared crystals of **tetrahydrated sodium diborate,** $NaBO_2.2H_2O$, or $Na_2O.B_2O_3.4H_2O$, by fusing a mol of the metaborate with two mols of sodium hydroxide, and allowing the aq. soln. to crystallize. M. Dukelsky showed the zone of stability of this salt to be *bcM*, Fig. 15; R. Benedikt prepared this salt by melting the higher hydrate in its water of crystallization, and drying the needle-like crystals in vacuo; and also by evaporating a soln. of borax with an excess of sodium hydroxide to a syrupy liquid, and allowing the product to crystallize. A. Rosenheim and F. Leyser confirmed M. Dukelsky's work as to the existence of the three salts, $Na_2O : B_2O_3 : H_2O = 1 : 1 : 8$; $1 : 2 : 10$; and $1 : 5 : 10$. A. Atterberg claimed to have made prismatic crystals of the two hydrates, $Na_2O.B_2O_3.4{\cdot}5H_2O$ and $Na_2O.B_2O_3.5{\cdot}5H_2O$, but there is no evidence that these products are not partially dehydrated octohydrates, or imperfectly dried tetrahydrates. Similar remarks also apply to J. J. Berzelius' hexahydrate, $Na_2O.B_2O_3.6H_2O$, which he claimed to have made as a confused mass of crystals, by melting the octohydrate in its own water of crystallization, and cooling the product to 0°. E. Bechi found a salt of a similar composition as an incrustation at the boric acid lagoons of Tuscany. According to J. J. Berzelius, an aq. soln. of the metaborate in hot water yields when slowly cooled in a covered vessel, large oblique rhombic prisms of **octohydrated sodium diborate,** $Na_2O.B_2O_3.8H_2O$, or $NaBO_2.4H_2O$. H. Hahn believed the crystals to be monoclinic; R. Benedikt, triclinic. C. F. Rammelsberg also made some observations on these crystals. M. Dukelsky represented the region of stability of this hydrate at 30° by the area *cdO*, Fig. 15. R. Benedikt also made crystals of the same salt by concentrating a boiling soln. of equi-molar proportions of sodium hydroxide and borax to a thin syrup, and leaving it to crystallize over conc. sulphuric acid. According to J. J. Berzelius, the crystals melt at 57° in their water of crystallization and on cooling, crystals of a lower hydrate are formed; when heated to

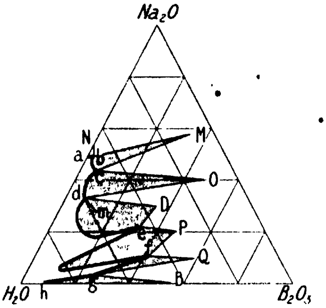

FIG. 14.—Ternary System, $Na_2O-B_2O_3-H_2O$, at 60°

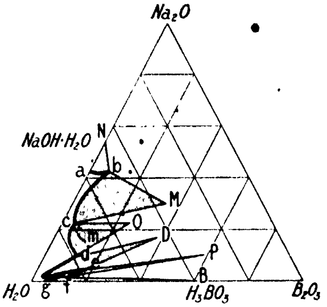

FIG. 15.—Equilibrium Conditions in the Ternary System, $Na_2O-B_2O_3-H_2O$, at 30°.

a still higher temp., the salt tumefies, forming a frothy mass, and at a still higher temp. R. Benedikt obtained a clear glass. The dehydrated salt rapidly absorbs carbon dioxide from the air, and is gradually converted into a mixture of borax and sodium carbonate. The same change occurs when the soln. is exposed to air, but when re-boiled the carbon dioxide is gradually expelled. H. S. van Klooster found that with lithium metaborate, melting at 843°, and about 42 molar per cent. of sodium metaborate, melting at 966°, there is a eutectic at 648°. H. V. Regnault found the sp. ht. to be 0·2571 between 17° and 97°. J. Thomsen's observations on the neutralization of boric acid with sodium hydroxide (*vide* boric acid) show that the heat developed is proportional to the quantity of alkali until the ratio Na : B=1 : 1 is attained, the heat developed then becomes small possibly owing to hydrolysis. L. Kahlenberg and O. Schreiner's and H. S. Shelton's measurements of the electrical conductivity and f.p. of soln. of sodium metaborate show that polyborates are probably formed. P. Walden measured the electrical conductivity, λ, of a soln. containing a mol of sodium metaborate in v litres of water at 25°, and obtained

v	32	64	128	256	512	1024
λ	73·3	77·8	81·4	84·3	86·9	89·1

and from the difference $\lambda_{1024}-\lambda_{32}$ he showed that metaboric acid is dibasic, although hydrolysis interferes with the application of Ostwald's rule. Aq. soln. of sodium metaborate react feebly alkaline, owing to hydrolysis—*vide infra.* L. Kahlenberg also said that the soln. contains but few hydroxyl-ions. E. Polenske obtained crystals of sodium metaborate with alcohol of crystallization, $Na_2O.B_2O_3.5CH_3OH$, in the residue obtained by distilling borax with methyl alcohol.

The mineral *tinkal* or *tincal* or crude *borax* was described by G. Agricola, and by J. G. Wallerius. It was originally brought to Europe from a salt lake in Tibet, where it occurs in the deposits from several lakes, and at Pugatal (Rupschn), there is a deposit about a metre thick containing sulphur, borax, sodium chloride, ammonium chloride, and magnesium and aluminium sulphates. The Thibetan deposits have been described by R. Saunders, and H. von Schlagintweit. The former described the extraction of tincal from the borax lake of Thibet. This lake is 20 miles in circumference, and is fed by springs and not by rivers and streams. It is frozen over for the greater part of the year. The tincal is deposited in the bed of the lake, and collected in the summer months from the shallowed depths and near the bank. Rock salt is also found in the deeper parts, but not in the shallows and borders. The cavities made by digging out the tincal soon fill up again. The following is from H. Vohl's analysis of tincal from Tibet:

H_3BO_3	Na_2O	K_2O	CaO	MgO	SiO_2	H_2O	Cl	H_2SO_4	Sand, etc.
36·89	16·48	0·013	0·24	0·19	0·05	44·64	0·17	0·22	0·78

In addition, alumina, 0·0013, and ferric oxide, 0·0068 per cent., with traces of manganese oxide, and carbon dioxide are found. The salt was originally purified in Holland, and France, and at Venice—hence the name *borax veneta.* Ordinary borax is **decahydrated sodium tetraborate**, $Na_2B_4O_7.10H_2O$, or $Na_2O.2B_2O_3.10H_2O$; and it is also called *sodium biborate or diborate.* Borax also occurs at Viquintizoa and Escapa in Peru; in the Sirdian steppe, Persia (H. Winklehner); at Halberstadt in Transylvania (J. D. Dana); in the Sambhar Lake, India; Kertsch and Taman (Russia) (W. S. Vernadsky and S. P. Popoff); and in Ceylon (J. R. Blum); near the soffioni of Tuscany (E. Bechi), but G. d'Achiardi found only traces of sodium in Bechi's samples at Pisa, at Chambly, and St. Ours in East Canada; in Borax Lake, in California, etc. The crude borax can be purified from earthy and fatty matters, sodium chloride, sodium sulphate, calcium borate, etc., by digestion with water, filtration, and crystallization. R. von Wagner removed the fatty matters by washing with a 5 per cent. soln. of sodium or calcium hydroxide; and M. Clouet, by calcination with 10 per cent. of sodium nitrate. A. Payen, G. Lunge, P. J. Robiquet and R. L. Marchand, and E. Durand have also described processes for purifying borax.

Before 1870, European borax was made by mixing a soln. of boric acid with the proper proportions of sodium carbonate, sodium hydroxide, or sulphide as described by F. Witting, F. Jean, A. Payen, or O. Köhnke. The range of stability of the salt at 30° is shown in Fig. 15, and at 60°, in Fig. 14. Borax crystallizes best when about an excess of 5 parts of soda crystals per 100 parts of borax is present—if the excess be too great, metaborate, $NaBO_2.4H_2O$, will be formed. If the hot liquid be to conc., octahedral borax, $Na_2B_4O_7.10H_2O$, will be formed. The best crystals are produced by very slowly cooling the hot soln. of the correct sp. gr. in large vats. Finely powdered borax is produced from the detritus of borax crystals, or by agitating the crystallizing liquid in small vats. Other processes have been suggested for converting boric acid into borax. For example, G. Lunge proposed fusing the boric acid with soda ash, digesting the product with water, and crystallizing the soln. The ammonium sulphate in Tuscany can be recovered as ammonium carbonate. H. N. Warren, and N. Tate suggested fusing the boric acid with sodium chloride—hydrogen chloride is a by-product. Heating the boric acid with sodium sulphate has also been tried.

The crude borax from the tincal beds, or salt marshes—*e.g.* Saline Valley, Inyo Co., Cal.—contains sand, sodium sulphate, carbonate, or chloride, admixed with 10–90 per cent. of borax. The process of purification is simple. It has been discussed by E. L. Fleming, C. N. Hake, etc. The surface to a depth of 18 ins. is mixed with boiling water in large iron pans. The clear liquor is run from the sediment into iron vats when the borax crystallizes out first; the mother liquor is conc. and again allowed to crystallize, after which it is allowed to run to waste. The borax in the waters of Searle's Lake, San Bernardino, Cal., is extracted by G. P. Burnham's process of fractional crystallization at different conc. and temp. so that the salts are separately deposited in different ponds. According to L. W. Chapman:

In Burnham's process several ponds are provided and the potash is made by running the brine into shallow ponds during the summer days, then into deep ponds at night in order to retain the heat. By continuing the process, the evaporation is maintained until the brine becomes sat. with KCl. At this point, the brine is circulated between two shallow ponds, and, on cooling at night, the potassium chloride crystallizes out in one pond, and during the day further evaporation of the sodium chloride crystallizes out in the other. Borax is made by running the brine into shallow ponds at night during the winter to cool, sodium sulphate and sodium carbonate being deposited. When the brine is coolest, in the early morning, it is run into deep ponds, where the temp. is maintained for several days, the borax gradually crystallizing out.

Borax is derived from colemanite of Death Valley and at Lang, near Los Angeles; from pandermite of Asia Minor; and from boronatrocalcite, ulexite, tiza, or cotton balls of Peru and Chili—Province of Atacama, and Ascotan, Maricunga, and Copiapó. The process for the extraction of borax from boronatrocalcite, and colemanite has been described by F. Witting, A. Kelly and R. B. R. Walker, F. M. Dupont, A. Campbell, L. Darapsky, A. Robottom, N. Gräger, etc. The manufacture involves four operations: (i) Boiling the ore with a soln. of sodium carbonate; (ii) lixiviating the filter-press mud to remove entrained borax; (iii) crystallizing the liquor; and (iv) working up the mother liquor from the crystallizing vats.

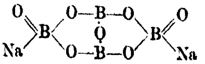
There are many modifications in detail in the different processes of extraction. In general, the crushed ore is powdered, and sifted. It is then transferred from the storage bins to the decomposing vats, where it is mixed with the mother liquid from the crystallizing vats and water. The right proportions of sodium carbonate and hydrocarbonate are added, and steam is introduced. After boiling for some time, the liquor is pumped through filter presses, and the clear liquor is run to the crystallizing vats with or without an intermediate settling vat. The mud from the filter presses is cleaned out. The crystallizing vats are filled with vertical iron rods hanging from bars. The rods are suspended in the liquor about 8 ins. apart. In about 8 days, the liquor is syphoned off, and the crystals are washed, broken from the rods and sides of the tank, dried, and granulated or powdered.

With pandermite, the powdered mineral, with the liquor, and sodium carbonate is boiled over-night in closed vessels at about 60 lbs. pressure; pandermite is also decomposed by heating it with a soln. of sodium carbonate in autoclaves. The calcium borate furnishes a soluble basic sodium borate which is afterwards mixed with enough boric acid to produce borax.

C. Bigot and J. Schreiter converted the natural calcium borate into sodium tetraborate by mixing it with lime, and decomposing the product with sodium sulphate; E. Dresel and J. Lennhof mixed the calcium borate with sodium chloride and ammonium borate, and digested the mass under press. with ammonia at 12°, when the sodium borate is precipitated; or they digested the mineral with ammonium tetraborate, sodium chloride and sulphate. U. Sborgi and C. Franco have studied the conditions which favour the right side of the system $(NH_4)_2B_4O_7+2NaCl \rightleftharpoons Na_2B_4O_7+2NH_4Cl$. C. Masson and C. Tillière proposed digesting the mineral with a soln. of ammonium hydrocarbonate or sulphate at 60° in an autoclave at 2 atm. press. A. A. Kelly and B. D. Jones calcined the ore with alkali and treated the mixture with water and carbon dioxide at atm. or an increased press. The alkali borate was crystallized by concentrating the aq. soln. K. Harding and B. D. Jones treated the boron mineral colemanite, boracite, ulexite, etc – with nitre cake and sulphuric acid. R. Rickmann and E. Rappe treated the calcium borate with sodium hydrofluosilicate, $3CaB_4O_7+Na_2SiF_6+4H_2O=3CaF_2+Si(OH)_4+Na_2H_4B_{12}O_{21}$. A. Schuster and M. Wilhelmy treated boronatrocalcite with fluorine, hydrofluoric acid, or a fluoride: $Na_2Ca_2B_8O_{15}+4HF = 2CaF_2+Na_2B_4O_7+2B_2O_3+2H_2O$; and they also proposed fusing the native borate with sodium hydrophosphate: $3CaB_4O_7+2Na_3PO_4=Ca_3(PO_4)_2+3Na_2B_4O_7$.

E. Schweizer[3] stated that if a soln. of borax be evaporated on a water-bath at 90°, an amorphous mass with 26·6 per cent. of water corresponding with *tetrahydrated sodium tetraborate*, $Na_2B_4O_7.4H_2O$, is formed. There is no particular reason for assuming that this partially dehydrated product is a chemical individual. The observations and analyses of J. J. Berzelius, A. Stromeyer, C. F. Rammelsberg, J. J. Ebelmen, J. Tunnermann, J. C. G. de Marignac, H. Rose, P. Bolley, T. J. Herapath, A. Laurent, and C. Tissier show that if borax soln. be crystallized below 60°–62°, **decahydrated sodium tetraborate,** $Na_2B_4O_7.10H_2O$, is formed, but if over that temp., **pentahydrated sodium tetraborate,** $Na_2B_4O_7.5H_2O$, appears. J. Ponomarev measured the m.p. of fused mixtures of borax and boron trioxide and found evidence of the formation of **sodium hexaborate,** $Na_2B_6O_{10}$, m.p. 694°, and of **sodium octoborate,** $Na_2B_8O_{13}$, m.p. 783°. There is a continuous series of solid soln. ranging from $Na_2B_4O_7$ to $Na_2B_8O_{13}$. E. Soubeiran and F. A. Pellerin first reported crystals of the pentahydrate; its range of stability at 60° is shown in Fig. 14. According to D. Gernez, if a supersaturated soln. of borax be allowed to evaporate spontaneously at ordinary or at elevated temp., the pentahydrate is formed. The supersat. soln. can be made by dissolving three parts of the ordinary decahydrate in 4 parts of warm water, and cooling the mixture rapidly in a flask with the contents protected from the dust; or a dil. soln. can be evaporated in vacuo, but in the latter case, care must be taken that undissolved particles of the decahydrate are not present. A. Payen recommended dissolving in water at 100° enough borax to form a soln. of sp. gr. 1·246; on cooling, the pentahydrate begins to separate at 79°, and continues to 56°, below this temp. the ordinary decahydrate is formed; on the other hand, a soln. of sp. gr. 1·17 gives nothing but the ordinary decahydrate. T. W. Richards and J. B. Churchill found that the transition temp. could not be located very precisely. E. Soubeiran, and F. A. Pellerin stated that if the soln. of the pentahydrate be boiled for some time it appears to yield more pentahydrate, even when cooled below 56°; but D. Gernez doubted this statement. C. Tomlinson found the undercooled soln. can be preserved at −17·8°. D. W. Horn and E. M. van Wagener showed that while the decahydrate and the metastable pentahydrate can be obtained side by side below 62°, only the pentahydrate crystallizes from soln. above this temp.

The unsaturated character of boric acid as a derivative of tervalent boron leads to the formation of stronger, polyboric acids which, according to J. Böeseken, must be derivatives of quinquevalent boron; and he writes the formula of borax:



but the direct union of sodium to boron in borax is not probable. Anhydrous borax orms a clear brittle glass—*borax glass*; but, according to C. H. Burgess and A. Holt, f borax glass be kept some hours at a temp. at which a viscid syrup is formed, small olourless needle-like crystals are formed. The **crystals** of borax were described by . F. Naumann in 1829, and by A. Lévy in 1837. The crystals of the decahydrate re monoclinic prisms, with axial ratios, according to C. F. Rammelsberg, $a:b:c$ $=1·0995:1:0·5629$, and $\beta=106°\ 35'$. Measurements were also made by H. Hahn, H. de Sénarmont, and by M. S. Miguel and M. de J. Nâranjo y Vega. A. Payen said that the crystals of the pentahydrate are octahedral, and hence the salt is often called *octahedral borax*, but this is a misnomer, since the crystals were shown by A. Arzruni to be hexagonal rhombohedrons belonging to the trigonal system, with the axial ratio $a:c=1:1·87$, and $\alpha=72°\ 2'$. G. Brügelmann reported mixed crystals with sodium chlorate and borax containing 89·19 per cent. $NaClO_3$, 4·7 per cent. $Na_2B_4O_7$, and 6·11 per cent. of water, but O. Lehmann showed that the two salts crystallize from the mixed soln. side by side. H. Baumbauer studied the analogies between the crystal forms of borax and diopside, and the **corrosion figures**; M. Kuhara investigated the **percussion figures** of borax. The **specific gravity** of anhydrous borax was stated by E. Filhol to be 2·367; by P. A. Favre and C. A. Valson, 2·371 at 20°; by P. P. Bedson and W. C. Williams, 2·368 at 16°, and 2·373 at 18·5°; G. Quincke gave 2·5 for the sp. gr. of borax glass; A. Payen gave 1·815 for the sp. gr. of the pentahydrate, and for the decahydrate, 1·74; R. Boyle gave 1·714; R. Kirwan obtained a similar result for the decahydrate; while R. Watson gave 1·757; J. H. Hassenfratz, 1·723; L. Playfair and J. P. Joule, 1·730 at 3·9°; E. Filhol, 1·692; H. J. Buignet, 1·692; F. Stolba, 1·7156 at 17°; P. A. Favre and C. A. Valson, 1·711 at 20°; W. C. Smith, 1·736; and J. Dewar, 1·694 at 17°, and 1·728 at −188°. The sp. gr. of aq. soln. with 2·08, 2·44, and 3·65 per cent. of $Na_2B_4O_7$ were found by P. P. Bedson and W. C. Williams to be respectively 1·0185, 1·0211, and 1·0331 at 20°; F. Forster found for 1·34 and 2·65 per cent. soln., 1·0105 and 1·0247 respectively at 25°. G. T. Gerlach gave for the soln. at 15°:

Per cent. decahydrate	0·5288	1·0576	1·5864	2·1152	2·6439	3·1727
Sp. gr.	1·0049	1·0099	1·0149	1·0199	1·0249	1·0299

F. Stolba found a soln. sat. at 17° had a sp. gr. 1·0208, and H. G. Greenish and F. A. U. Smith 1·020 at 16·5°. Measurements were also made by F. Fouqué, and by A. Michel and L. Krafft. The **hardness** of the decahydrate is 2·0–2·5 on Mohs' scale, and A. Payen said that the pentahydrate is harder than the decahydrate. G. Quincke gave for the **surface tension** of fused borax at 1000°, 211·9 dynes per cm., and for the **specific cohesion**, $a^2=17·28$ per sq. mm.

Borax glass becomes opaque on exposure to air, owing to the absorption of moisture; indeed, H. V. Blücher found that after powdered borax glass had been exposed for a few months to air, it was completely converted into the decahydrate; but C. H. Burgess and A. Holt found that the needle-like crystals of anhydrous borax are non-hygroscopic.

The decahydrate effloresces superficially in dry air, and becomes opaque; the crystals of the pentahydrate were found by A. Payen to absorb water and become opaque; while D. Gernez found that they remain transparent even in air sat. with moisture, if dust is excluded, but in ordinary atm. air, they become white and some decahydrate is formed. The decahydrate decrepitates when heated, but, according to A. Payen, the pentahydrate does not. A. Atterberg found that when the decahydrate is heated to 80°, it loses four-fifths of its water, and at 100° more water is continuously given off, and all is lost at 200°; the pentahydrate was found by D. Gernez to lose part of its water at 57°. When the decahydrate is heated, it tumefies, swelling up to a spongy mass called *borax usta*, or *calcined borax*; at a higher temp. this runs together, forming a clear colourless glass—*borax glass*. V. Meyer and W. Riddle said that the **melting point** of borax glass is 878°; T. Carnelley, 561°; J. Ponomarev, 730°; and A. L. Day and co-workers, 741°. The glass, of course, has not a true m.p., it gradually softens on a rising temp.;

C. H. Burgess and A. Holt found the crystals of the anhydrous salt melt at a higher temp. than the glass.

Borax is lost by **volatilization** during calcination; the proportion lost depends on the magnitude of the exposed surface, and the duration of the heating; thus S. Walbott found, by heating 0·6532 grm. of borax glass in a crucible over a gas-blowpipe flame:

Time . . .	5	12	22	29	39	44	46 mins.
Loss . . .	0·8	1·0	2·0	2·5	3·3	4·1	4·2 per cent.

and E. Cramer found at about 1200°:

Time	3	26	48	60 hrs.
Loss	1·47	7·88	22·40	48·98 per cent.

T. H. Norton and D. M. Roth said that in the hottest part of a Bunsen's flame, sodium chloride volatilizes 16·54 times as fast as borax. H. Lescœur measured the **vapour pressure** of the hydrates of sodium tetraborate, and obtained indications of the formation of a di-, penta-, and a deca-hydrate. E. Löwenstein made some remarks on this subject. E. Jänecke also claimed to have formed **dihydrated sodium tetraborate,** $Na_2B_4O_7.2H_2O$, by compressing the pentahydrate which melts under the operation.

According to G. Tammann, the lowering of the vap. press. of aq. soln. of 5·78, 19·07, and 50·22 grms. of borax, $Na_2B_4O_7$, per 100 grms. of water are respectively 13·5, 32·4, and 63·2 mm. G. T. Gerlach measured the **boiling point** of soln. containing *g* grms. of $Na_2B_4O_7$ grms. of water, and found:

g . . .	8·64	17·2	26·5	37·5	48·5	61·2	90·8	112·3
B.p. . . .	100·5°	101°	101·5°	102°	102·5°	103°	104·0°	104·6°

The soln. boiling at 103° is sat., those boiling at a higher temp. are supersaturated. T. Griffiths placed the b.p. of a sat. soln. at 105°. L. Kahlenberg and O. Schreiner, and H. S. Shelton measured the lowering of the **freezing point** of aq. soln. of borax, and found with 0·0125, 0·0250, 0·0500, and 0·1000 mol of borax per litre, a mol. depression respectively of 10·6°, 9·7°, 8·6°, and 7·2°. The high values in the more dil. soln. are taken to show that the mol dissociates as symbolized by: $Na_2B_4O_7+H_2O\rightleftharpoons 2Na^{\cdot}+2BO_2'+2HBO_2$.

H. V. Regnault gave 0·2382 for the **specific heat** of borax glass between 16° and 98°, and H. Kopp, 0·229 between 17° and 47°; the latter also gave 0·385 for the sp. ht. of the decahydrate between 19° and 50°. M. Berthelot gave 74·81 Cals. for the **heat of formation** of the anhydrous salt from its elements; W. G. Mixter gave for $3Na_2O+B_2O_3=2Na_3BO_3$ +104·2 Cals. P. A. Favre and C. A. Valson found 10·2 Cals. for **heat of solution** of the anhydrous salt; and −23·9 Cals. for the decahydrate; J. Thomsen found −25·9 Cals. for the heat of soln. of a mol of the decahydrate in 1600 mols of water. Hence, the **heat of hydration** is 34·1 Cals.

The **refractive index** of isotropic borax glass was found by P. P. Bedson and W. C. Williams to be 1·5216 for the H_α-line; 1·5147 for the Na-line; and 1·5139 for the H_β-line. H. Dufet gave for crystals of the decahydrate:

	F-line	Tl-line	Na-line	C-line	Li-line
α	1·4517	1·4491	1·4467	1·4445	1·4441
β	1·4750	1·4719	1·4694	1·4669	1·4665
γ	1·4778	1·4778	1·4724	1·4699	1·4695

Measurements have also been made by D. Brewster, A. des Cloizeaux, F. Kohlrausch, and G. Tschermak. The crystals of the pentahydrate have a positive **double refraction,** that of the decahydrate is negative. According to H. de Sénarmont, the decahydrate shows a well-defined *dispersion croisée*. J. H. Gladstone and W. Hibbert found the **molecular refraction** of fused borax to be 42·80 for the *A*-line, and 42·83 in sat. soln. F. Forster gave 0·1663 for the specific refraction. A. Schrauf studied the absorption of vibrations in different directions in the crystals of borax.

H. Murschhauser found that the specific rotation of soln. of glucose and borax decreased as the conc. of the soln. increased.

C. Doelter found the crystals to be fairly transparent to **X-rays**, being about the same as corundum, and less than boric acid. A sample of borax from Mono Lake was found by C. Baskerville to phosphoresce in **ultra-violet light**—probably the effect of certain impurities because no other sample showed any phosphorescence. W. W. Coblentz found the **ultra-red transmission spectrum** of borax glass gave bands at 1·9μ, 3μ, 3·7μ, and 4·8μ ; and in the reflection spectrum wide maxima at 7·5μ and 10μ. According to E. Tiede and co-workers, when boric acid is mixed with certain organic substances, particularly aromatic and heterocyclic substances, and partly dehydrated by melting, it is found on cooling that the mixtures are strongly phosphorescent. These substances after illumination by ultra-violet light emit a phosphorescent glow of a colour which varies with the organic substance and in the best cases persists for two to three minutes after the exciting light is removed.

According to P. Burckhard,[4] molten borax conducts electricity, and during electrolysis, oxygen is given off at the anode, and at the cathode, a gas which burns with a yellow flame is given off ; if a platinum cathode is used, platinum boride is formed. A. Z. Hartmann also studied the electrolysis of molten borates. P. Walden found the eq. **electrical conductivity,** λ, and H. C. Jones the mol. conductivity, μ, of an aq. soln. of borax with a mol of the salt in *v* litres of water, at 0° to 65° to be :

v .	16	32	128	512	1024	2048	4096
μ_{0°	57·99	64·36	72·87	78 04	79·20	83·45	85·50
μ_{15°	113·54	125·49	141 72	152·00	153·40	161·23	163·99
μ_{65°	231·3	256·2	281·6	316·7	—	359·3	

The calculated percentage **degrees of ionization,** α, are :

v .	16	32	128	512	1024	2048	4096
α_{0°	67·8	75·3	85·3	91·3	92 7	97·6	100·0
α_{15°	69·2	76·5	86·4	92·7	93 5	98·3	100·0

The assumptions on which the calculations are based are wholly inadequate on account of hydrolytic and other disturbing reactions. H. C. Jones also calculated the temp. coeff. of the conductivity for soln. of different conc. L. Kahlenberg and O. Schreiner, A. A. Noyes and W. R. Whitney, and H. S. Shelton found that with soln. made up from borax ; or from the corresponding amounts of sodium metaborate and boric acid ; or from sodium hydroxide and boric acid, both the lowering of the f.p. and the conductivity determinations agree that the borax is probably ionized in dil. aq. soln.: $Na_2B_4O_7+H_2O=2Na^{\cdot}+2BO'_2+2HBO_2$. The univalency of the borate-ions in soln. was tested by P. Walden's application of Ostwald's rule for the mol. conductivity of soln. of the sodium salt: $\mu_{1024}-\mu_{32}=13·5$; this value is greater than that required for univalent ions ; but the discrepancy was attributed to disturbances due to hydrolysis. F. Auerbach showed that with conc. soln. complexes are formed. P. Müller and R. Abegg calculated that at 25°, a soln. of borax with the conc. expressed in mols per litre :

Conc. of Na˙-ion	0·050	0·090	0·206
Conc. of free boric acid	0·043	0·058	0·066
Conc. of boric acid in polyborates	0·007	0·041	0·140

The work of A. Atterberg, M. Dukelsky, etc., has shown that a polyborate of the type $Na_2O.5B_2O_3.10H_2O$ is formed in conc. soln. Besides the equilibrium between the different borate ions in aq. soln., the salt is hydrolyzed. As shown by C. Herzog, the dissociations of the salt in aq. soln. into acid and base is evidenced by soln. colouring red litmus blue, and turning turmeric brown. As shown by H. Rose, J. Shields, L. C. Barreswil, W. Henneberg, J. Bottomley, P. Georgievic, etc., the hydrolysis explains the action which the feeblest of acids and the halogens exercise on soln. of borax. J. Walker estimated that a 0·1*N*-$NaBO_2$ soln. was 0·84 per cent. hydrolyzed, and J. Shields, that a 0·1*N*-$Na_2B_4O_7$ soln. is between 0·3 and 0·5 per cent. H. Menzel found the degree of hydrolysis of *M* molar soln. to be:

M	0·4	0·2	0·1	0·04	0·02	0·01
Per cent. hydrolysis . .	0·50	0·57	0·76	1·22	1·70	2·30

He also studied the equilibrium conditions in the reaction $2Na_2CO_3+Na_2B_4O_7+H_2O \rightleftharpoons 2NaHCO_3+4NaBO_2$. R. Abegg and A. J. Cox have computed the solubility product of the soln. A. Schrauf studied the **magnetic axes** of the crystals. G. Meslin found borax to be diamagnetic.

In measuring the **solubility** of borax, G. J. Mulder[5] found 100 parts of water at 0° dissolve 1·4 and at 100°, 55·3 parts of anhydrous borax. Y. Osaka found 100 grms. of water at 25° dissolve 3·33 grms. of $Na_2B_4O_7$. Measurements were also made between 0° and 100° by A. B. Poggiale. D. W. Horn and E. M. van Wegener found that the solubility, *S*, with soln. crystallized from supersaturation, expressed in grams per 100 grms. of $Na_2B_4O_7$, is:

	0·5	10	30	50	60	62	65	70	80	100
S .	1·3	1·6	3·9	10·5	19·4	22	24	24·4	31·4	52·3
Solid phases	$Na_2B_4O_7.10H_2O$						$Na_2B_4O_7.5H_2O$			

The results are graphed in Fig. 16. The transition temp., $Na_2B_4O_7.10H_2O \rightleftharpoons Na_2B_4O_7.5H_2O+5H_2O$, is very nearly 62°, *O*, Fig. 16. J. H. van't Hoff and W. C. Blasdale said that in the presence of sodium chloride the transition temp. can be reduced to 35·5°. H. Lescœur is of the opinion that at 125°, the pentahydrate passes into **dihydrated sodium tetraborate,** $Na_2B_4O_7.2H_2O$. A. Rosenheim and F. Leyser gave 0·14 mol per litre for the solubility of sodium diborate at 0°. M. Dukelsky studied the ternary system $Na_2O-B_2O_3-H_2O$, at 30°; and U. Sborgi and F. Mecacci, the same system at 60°. J. H. van't Hoff and W. C. Blasdale found that in aq. soln. a mixture of sodium chloride and potassium borate forms potassium chloride and sodium borate at 25° and 83°. Table II shows the composition of soln.—mols of salt per 1000 mols of water sat. with borax and sodium chloride, and the salts indicated.

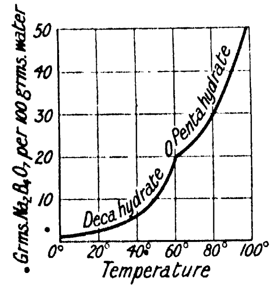


FIG. 16.—Solubility Curve of Borax in Water.

TABLE II.—COMPOSITION OF SATURATED SOLUTIONS OF BORAX AND SOME OTHER SALTS.

Soln. sat. with borax sodium chloride, and	Na_2Cl_2	K_2Cl_2	Na_2SO_4	$Na_2B_4O_7$	Na_2Cl_2	K_2Cl_2	Na_2SO_4	$Na_2B_4O_7$

According to D. S. Wester and A. Bruins, 100 grms. of *trichloroethylene* dissolve 0·011 grm. of sodium tetraborate at 15°. A. Stromeyer found that borax is virtually insoluble in absolute *alcohol*, but readily dissolves in an alcoholic soln. of *sodium acetate*, while, according to the U.S. Pharmacopœia, 100 grms. of alcohol, sp. gr. 0·941, dissolve 2·48 grms. of sodium borate at 15·5°; A. Vogel found that 100 parts of *glycerol* of sp. gr. 1·225 dissolve 6·7 parts of borax; and, according to the U.S. Pharmacopœia, (1907), 100 grms. of glycerol dissolve 60·3 grms. at 15·5°, and 100 grms. at 80°.

L. F. Kebler showed that glycerol and other polyhydric alcohols decompose a soln. of borax into sodium metaborate and boric acid. Molten borax glass dissolves many **metallic oxides,** which impart characteristic colours in oxidizing and reducing atm. Hence the use of borax in qualitative blowpipe analysis; and as a flux in soldering. H. Rose found that ferric oxide crystallizes from the soln. as magnetic oxide of iron; and titanic oxide, as rutile. G. Wunder also found that the oxides of the alkaline earths furnish characteristic crystals. J. J. Berzelius, A. Knop, and C. H. Burgess and A. Holt have studied this subject.

According to M. Faraday, a soln. of borax first reddens turmeric paper because of the excess of alkali; but as the colouring matter becomes altered by the presence of boric acid, the tint bcomes dirty blue, and the paper then behaves towards acids and alkalies just as if it had been cooled by boric acid—*q.v.* An aq. soln. of borax is decomposed by **chlorine** into sodium hypochlorite; and when evaporated with **hydrochloric acid** on a water-bath it is all decomposed into sodium chloride and boric acid. J. L. Gay Lussac,[6] and A. Laurent found that when an aq. soln. of borax coloured blue with litmus, is titrated with **sulphuric acid,** the blue colour changes to claret-red, and finally red when all the sodium has been converted to sulphate. H. Rose said that when a soln. of borax which has been made feebly acid is diluted with hot water, it again reacts alkaline—J. Joulin did not confirm this statement. According to E. Schweizer, when an aq. soln. of borax is sat. with **hydrogen sulphide,** sodium sulphide and free boric acid are formed. No borax is precipitated when the soln. is treated with alcohol; and when shaken with ether, two layers appear—the lower layer contains sodium sulphide, the upper layer boric acid; similarly, an aq. soln. of borax absorbs **carbon dioxide** until all the sodium is converted into carbonate, when the soln. reacts acid; alcohol does not precipitate borax from this soln., but when evaporated, the carbon dioxide is expelled, and borax remains. According to E. D. Clarke, a mixture of borax glass and **carbon** boils in the oxy-hydrogen flame giving off a white smoke, and forming a substance which becomes white on exposure to air. H. Murschhauser studied the effect of borax on the mutarotation of sugar. Gelatinous **silicic acid** does not act on a soln. of borax, but **organic acids** displace the boric acid. C. J. B. Karsten stated that when borax is triturated with **ammonium chloride,** ammonia is produced. According to G. Dragendorff, when a mixture of **phosphorus** and powdered borax glass is heated to redness, a dark brown glass is formed from which boron separates when agitated with water. C. Winkler found that when a mixture of borax and **magnesium** powder is heated in the absence of air, sodium, sodium metaborate, magnesium oxide, and magnesium boride are produced. A. Laurent stated that when **iron** is heated with borax glass a combustible gas is given off. T. Bergman added that when a soln. of borax is dropped into metallic salt soln., freed as much as possible from acid, sparingly soluble borates are precipitated from soln. of mercury, lead, copper, iron, tin, nickel, cobalt, and zinc; but soln. of gold, platinum, bismuth, and manganese remained undisturbed. W. Ackermann prepared what he called *boric acid water-glass* by gently warming a mixture of boric acid and borax in the proportions of 1 : 3. The product is supposed to be analogous to ordinary water-glass, and to be a colloidal soln. of boric acid in borax. The aq. soln. is rather less stable than ordinary water-glass, for it tends to solidify, and crystallize on standing, especially if shaken. It is said to have several advantages over borax as a flux in soldering.

Some uses of borax.—Borax and boric acid have an extraordinary number of applications in different industries.[7] They are used as constituents in making enamels for iron, and other metals; in the manufacture of pottery glazes; in making glass, artificial gems and strass; and in the manufacture of pigments for glass painting. Borax is used in making Guignet's green. It is employed in the tannery, and in the currying shops for dissolving dirt and blood from skins and thus ensuring a more rapid liming. It is used for cutting oils and fats used in stuffing leather and in bleaching and mordanting leather. It is used in the laundry in washing and starching; it helps to give linen a high gloss. Many commercial starches contain borax; and borax is also used in making some soaps. Borax is used as a wood preservative against dry rot, and on account of its antiseptic qualities it is introduced in cosmetics, mouth-washes, tooth-powders, and salves. It is used as a constituent of powders for killing insects, etc. It is employed as a preservation for meats, fish, and other food-stuffs. A varnish for stuffing hats is made from borax and shellac. A mixture of casein and borax is a substitute for gum and it is moisture-proof. The paper mills use borax in making a kind of parchment, and borax is used in making sizes and coatings for glazed papers and playing cards. Borax is used as a stiffening agent for the wicks of stearin candles; and it is also used in calico-printing. On account of the solvent action of fused borax on metal oxides, it is used for keeping a clear surface in the welding and brazing of metals. It is also used as a flux in many other operations; and in blowpipe analysis. Borax is employed in making manganese borate to be used as a drying agent for oils.

In addition to the tetraborates, represented by borax, other still more acid borates have been reported. According to L. Barthé,[8] when a boiling soln. of equal parts of borax and boric acid is cooled, the first crop of crystals has the composition: $2Na_2O.3B_2O_3$; the second crop, $Na_2O.2B_2O_3$; and the third crop, $2Na_2O.5B_2O_3$. These products are in all probability mixtures. L. Spiegel found that soln. of borax containing an excess of boric acid deposit crystals of **sodium hexaborate**, $Na_2O.3B_2O_3.nH_2O$, and he found a sample of commercial borax which he assumed to contain this salt because of its high B_2O_3 content. I. F. Ponomarev also examined the hexaborate. H. le Chatelier reported the formation of **sodium octoborate**, $Na_2O.4B_2O_3.nH_2O$, apparently analogous with the corresponding lithium salt. P. A. Bolley prepared what he regarded as the decahydrate by boiling a soln. of two eq. of borax with one eq. of ammonium chloride. If the soln. is moderately dil., ammonia gas is evolved, and when the evolution of gas has ceased, the filtered soln. furnishes milk-white or transparent crystals. I. F. Ponomarev also examined the octoborate. Analyses by A. Laurent, and P. A. Bolley agree with the formula $Na_2O.4B_2O_3.10H_2O$. The crystals lose water when heated, but do not swell up so much as borax; 100 parts of water dissolve 17–20 parts of the salt. The soln. is neutral to litmus.

The aq. soln. precipitates boric acid when treated with dil. acids, and it gives precipitates with those salts which gave precipitates with soln. of borax; although the products sometimes differ in colour and solubility both lose boric acid when washed with water. A. Atterberg believed that P. A. Bolley's salt is a mixture of tetra- and deca-borates.

A. Atterberg found that a soln. of a mol of sodium hydroxide with 5 mols of boric oxide deposits small prismatic crystals of **decahydrated sodium decaborate**, $Na_2O.5B_2O_3.10H_2O$ also called *sodium pentaborate*. The first crop of crystals contains a little boric acid; and the last crop a little borax. M. Dukelsky prepared this salt and showed the conditions of stability at 30°—*vide* Fig. 15. Judging from U. Sborgi and F. Mecacci's study at 60°, the salt does not appear to be stable at 60° in aq soln. M. Dukelsky, and A. Rosenheim and F. Leyser, as indicated above, also prepared decahydrated sodium decaborate, $Na_2O.5B_2O_3.10H_2O$. The solubility at 0° is 10·3 mols per litre. A. A. Kelly and B. D. Jones prepared the decaborate by passing sulphur dioxide into a mixture of 100 parts boronatrocalcite and 400 parts of water: $Na_2O.2CaO.5B_2O_3+3SO_2=2CaSO_3+Na_2SO_3+5B_2O_5$. The calculated amount of boronatrocalcite is added, and the mixture boiled: $Na_2O.2CaO.5B_2O_3+2(Na_2SO_3+5B_2O_3)=2CaSO_3+3(Na_2O.5B_2O_3)$. The borate may be recovered by crystallization. W. Voss obtained the decaborate by treating boronatrocalcite with sufficient sulphuric and boric acids to form the required salt. A. Atterberg found the crystals rapidly lose 6 mols of water at 80°, and slowly two mols more; at 200°, one mol of water is still retained, but at higher temp. all the water is expelled with intumescence. A. Atterberg believes this salt is the same as that prepared by A. Laurent, to which the formula $5Na_2O.24B_2O_3.55H_2O$ was assigned.

J. Tünnermann reported hydrated **sodium dodecaborate**, $Na_2O.6B_2O_3.nH_2O$—water 30 per cent.—to be formed in tabular crystals by adding boric acid to an aq. soln. of borax until the soln. no longer reddens turmeric, and evaporating and cooling. The salt tastes like nitre, and is neutral to vegetable colours; it swells up when heated, and melts to a clear glass. A. Laurent stated that if 2 mols of sulphuric acid are added to 3 mols of borax, the mixture does not redden litmus because the dodecaborate is formed, but with another mol of sulphuric acid the soln. reddens litmus because boric acid is liberated, and with another op of sulphuric acid, the litmus is coloured bright red from the excess of the last-named id. A. A. Noyes and W. R. Whitney infer the formation of complex borates as high as the odecaborate because the heat of neutralization of sodium hydroxide with boric acid steadily creases up to this proportion.

J. A. Arfvedson,[9] H. Rose, C. L. Bloxam, and N. Tate measured the amount of carbon dioxide expelled when boric acid is fused with potassium carbonate, from which it appears that at a dark red heat a mol of B_2O_3 drives out one mol of carbon dioxide from an excess of the carbonate, and at a bright red heat, 1·08-1·26 mol of carbon dioxide. C. L. Bloxam found that when boric acid is boiled with an aq. soln. of the carbonate three mols of B_2O_3 decompose one mol of potassium carbonate. C. L. Bloxam measured the water evolved when boric oxide is fused with potassium hydroxide, and found: $B_2O_3+4KOH=2K_2O.B_2O_3+2H_2O$. There is no other evidence of the formation of a basic carbonate. M. Dukelsky studied the ternary system, $K_2O.B_2O_3.H_2O$, at 30°, and his results are shown graphically in Fig. 17. The area *Kab* refers to the solid phase $KOH.2H_2O$; *bMc*, to the phase $K_2O.B_2O_3.2\frac{1}{2}H_2O$; *cDd*, to the solid phase $K_2O.2B_2O_3.4H_2O$; *dPe*, to the solid phase $K_2O.5B_2O_3.8H_2O$; and *eBf*, to solid boric acid, $B(OH)_3$.

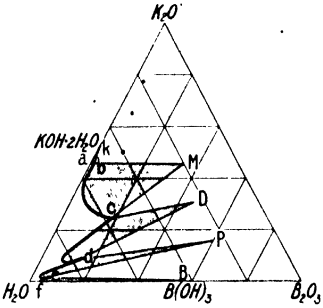

Fig. 17.—Equlibrium in the Ternary System, $K_2O-B_2O_3-H_2O$, at 30°.

As already indicated, J. A. Arfvedson, H. Rose, etc., found that a mol. of boric oxide will displace approximately a mol. of carbon dioxide from an excess of potassium carbonate at a red heat; and this was taken to show that **potassium metaborate or diborate,** $K_2O.B_2O_3$, or KBO_2, is formed; and J. J. Berzelius fused eq. proportions of carbonate and boric oxide or acid at a white heat. J. Schabus also prepared monoclinic plates of this salt with axial ratios $a:b:c=2·7440:1:2·6760$, and $\beta=93°\ 54'$. J. J. Berzelius added that the salt dissolves in water with difficulty, and does not crystallize from the soln.: it has a caustic alkaline taste and absorbs carbon dioxide from the air, forming a mixture of potassium carbonate and the tetraborate $K_2O.2B_2O_3$. A. Atterberg prepared what he regarded as a trihydrate, $K_2O.B_2O_3.3H_2O$, by dissolving the anhydrous compound in water, and evaporating it over sulphuric acid with an excess of potassium hydroxide. The microscopic crystals lose their water when heated, without changing their form, and the residue melts at a white heat, being much less fusible than the more acid salt. S. Motylewsky found the drop-weight of the molten salt to be 155 when that of water at 0° is 100 mgrms. H. S. van Klooster, and F. M. Jäger gave 947° for the m.p. of potassium metaborate. The surface tension at 992° is 123·5 ergs per sq. cm., and at 1142°, 96·6 ergs per sq. cm. A. Atterberg found that the salt volatilizes rapidly at a white heat. The fused salt forms needle-like crystals on cooling. It absorbs much gas while being melted, and this is rejected on cooling, thus causing some decrepitation. The salt deliquesces in air, absorbing carbon dioxide as well as water. It would appear that this salt is probably the same as the hemipentahydrate, $K_2O.B_2O_3.2\frac{1}{2}H_2O$, of M. Dukelsky, the zone of stability of which in aq. soln. at 30° is indicated by the area *bcM*, Fig. 17. A. Rosenheim and F. Leyser gave the solubility of the diborate as 0·9 mol per litre at 0°.

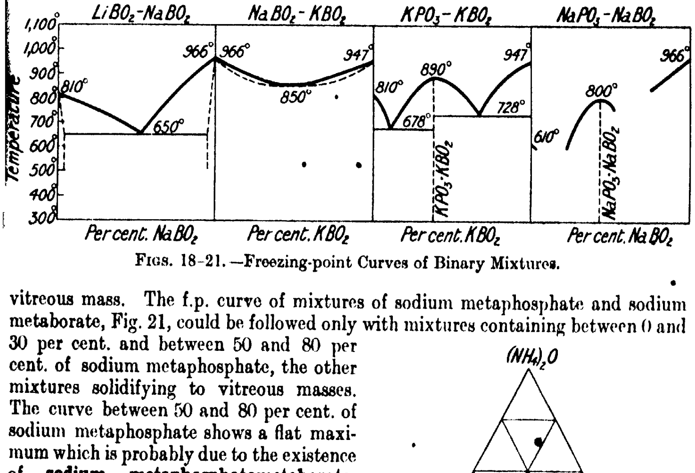
A. Atterberg obtained the **tetrahydrated potassium tetraborate,** $K_2O.2B_2O_3.4H_2O$, monoclinic prisms which, when heated, lost their water with intumescence, and finally fused to a clear glass, which H. J. Buignet found to have a sp. gr. 1·74. M. Dukelsky showed that the zone of stability of the tetrahydrate in aq. soln. is represented by the area *cDd*, Fig. 17. A. Laurent made a pentahydrate, $K_2O.2B_2O_3.5H_2O$, in hexagonal prisms by crystallization during the cooling of a boiling soln. of potassium carbonate mixed with an excess of boric acid, and made alkaline with potassium hydroxide. The first crop of crystals contain the octohydrated hexaborate, but afterwards the tetraborate alone appears. The salt dissolves readily in hot and cold water; it tastes slightly alkaline, reddens turmeric; tumefies when heated; and finally fuses to a clear glass. A. Atterberg reported a hemihenadecahydrate, $K_2O.2B_2O_3.5\frac{1}{2}H_2O$, to be formed in hexagonal prisms by evaporating at ordinary temp. the aq. soln. of a fused mixture of eq. proportions of the component salts. A. Laurent, and A. Atterberg also reported monoclinic prisms of the hexahydrate, $K_2O.2B_2O_3.6H_2O$, which lost 2 mols at 75°; 2 mols more at 100°; and which retained one mol of water at 200°. M. Dukelsky obtained no evidence of any other than the tetrahydrate at 30°, so that the penta- to the hexa-hydrates were possibly the tetrahydrate with entrained water. A. Rosenheim and F. Leyser made **potassium pentaborate** with a solubility of 0·07 mol per litre at 0°.

H. Schiff observed that the aq. soln. of the tetraborate absorbs much iodine to form a colourless soln. Potassium iodide and iodate are formed in accord with the equation $9K_2B_4O_7+3I_2=6K_2B_6O_{10}+5KI+KIO_3$; as well as hydrated **potassium hexaborate,** $K_2O.3B_2O_3.nH_2O$. W. Reissig prepared what he regarded as the pentahydrate, $K_2O.B_2O_3.5H_2O$, by cooling to 6° a boiling soln. of a mol of potassium carbonate with 2 mols of boric oxide. The rhombic prisms so obtained have the axial ratios $a:b:c=0·5285:1:0·9206$; and are stable in air. A. Laurent obtained what he regarded as the octohydrated hexaborate, $K_2O.3B_2O_3.8H_2O$, during the preparation of the tetraborate. The rhombic prisms have the axial ratios $a:b:c=0·77:1:0·70$; they are stable in air; and readily melt with intumescence. A. Atterberg believes that A. Laurent's salt is really the decaborate. M. Dukelsky observed no signs of formation of a hexaborate in aq. soln. at 30°. H. le Chatelier prepared what he regarded as **potassium octoborate,** $K_2O.4B_2O_3$, by a process analogous to that he employed for the lithium salt.

C. F. Rammelsberg obtained crystals of **octohydrated potassium decaborate,** $K_2O.5B_2O_3.8H_2O$, from a boiling aq. soln. of potassium hydroxide sat. with boric acid. A. Laurent gave the formula $5K_2O.24B_2O_3.55H_2O$. J. Böeseken represented the salt KB_5O_8 by the graphic formula $K{-}B{=}(OBO)_4$, with one boron atom quinquevalent. A. Laurent found that the rhombic crystals had the axial ratios $a:b:c=0·9709:1:0·8054$. V. von Lang also measured the crystals which have a positive double refraction. M. Dukelsky found the region of stability of the crystals in aq. soln. at 30° to be represented by *dPe*, Fig. 17. According to A. Atterberg, the crystals rapidly lose 6 mols of water at 100°, and still more water is lost slowly; at 200°, one mol of water is still retained; at a red heat, the salt forms a clear glass. When treated with hydrofluoric acid, potassium borofluoride is formed. A. Laurent stated that rhombic prisms of *decahydrated potassium dodecaborate*, $K_2O.6B_2O_3.10H_2O$, crystallize from neutral soln. of potassium hydroxide and boric acid. He said that the crystals are permanent in air; turn reddened litmus slightly blue; dissolve sparingly in cold water and copiously in hot water. A. Atterberg tried to make this salt from soln. containing 3, 4, 5, and 6 mols of boric oxide to one mol of K_2O, but obtained in every case, octohydrated potassium decaborate; nor did M. Dukelsky obtain any evidence of a dodecaborate in aq. soln. at 30°.

A. C. Reischle [10] prepared anhydrous **rubidium tetraborate,** $Rb_2B_4O_7$, by precipitating an alcoholic soln. of rubidium oxide with a similar soln. of boric acid. The free crystalline precipitate contains alcohol of crystallization. W. Reissig, and A. C. Reischle prepared the **hexahydrated rubidium tetraborate,** $Rb_2B_4O_7.6H_2O$, by dissolving 2 mols of boric acid and one mol of rubidium carbonate in boiling water; rhombic six-sided plates separate during the cooling of the soln.; and they are stable in air. A. C. Reischle obtained **cæsium hexaborate,** $Cs_2B_6O_{10}$, or $Cs_2O.3B_2O_3$, by mixing alcoholic soln. of cæsium oxide, and boric acid. The crystals separate slowly from the soln. A. Rosenheim and F. Leyser made **rubidium pentaborate.**

According to H. S. van Klooster, the f.p. curve of mixtures of lithium and sodium metaborates, Fig. 18, gives no indication of the formation of a compound, but there is a eutectic at 650° with 52 per cent. of lithium metaborate. The miscibility of the crystals is very limited, for **lithium metaborate** dissolves 2 per cent. of sodium metaborate, and the latter 3 per cent. of the lithium salt. Mixtures of sodium and potassium metaborates give a f.p. curve, Fig. 19, showing a continuous series of mixed crystals, and having a flat minimum with 50 per cent. of sodium metaborate. There is evidence of a decomposition of the mixed crystals between 522° and 553° with mixtures with 40 to 60 per cent. of sodium metaborate. The f.p. curve, Fig. 20, of mixtures of potassium metaborate and metaphosphate possesses two eutectics at 681° and 770° respectively, the former corresponding with 90 per cent. and the latter with 30 per cent. of potassium metaphosphate. The portion of the curve between the eutectics rises to a very flat maximum, extending between 50 and 60 per cent. of potassium metaphosphate. The eutectic arrest is only noticeable in the neighbourhood of the eutectics, so that it cannot be used to determine the position of the maximum. The composition agrees with **potassium metaphosphatometaborate**, $KPO_3.KBO_2$. Fusions of this composition give neutral soln., whereas with higher and lower percentages of potassium metaphosphate they are respectively acid and alkaline. The presence of the compound KPO_3,KBO_2 is also indicated by the microscopic examination of thin sections. Fusions containing between 65 and 85 per cent. potassium metaphosphate would not crystallize, but they solidified to a vitreous mass. The f.p. curve of mixtures of sodium metaphosphate and sodium metaborate, Fig. 21, could be followed only with mixtures containing between 0 and 30 per cent. and between 50 and 80 per cent. of sodium metaphosphate, the other mixtures solidifying to vitreous masses. The curve between 50 and 80 per cent. of sodium metaphosphate shows a flat maximum which is probably due to the existence of **sodium metaphosphatometaborate**, $NaPO_3.NaBO_2$, further evidence in support of the existence of which is given by chemical and optical investigations similar to those described for the potassium compounds. Conductivity measurements showed that this compound also exists in soln. to some extent.



FIGS. 18-21.—Freezing-point Curves of Binary Mixtures.

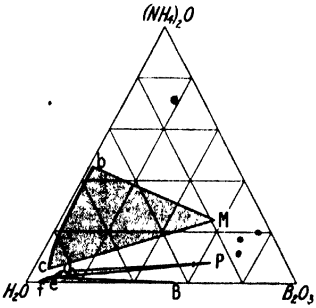


FIG. 22.—Equilibrium in the Ternary System, $(NH_4)_2O—B_2O_3—H_2O$, at 30°.

Eleven **ammonium borates** have been described; but U. Sborgi[11] could find only three in his study of the ternary system $(NH_4)_2O—B_2O_3—H_2O$, at 30°. He found the 1 : 4 : 6 compound at 60°, and the 1 : 2 : 4 and the 1 : 5 : 8 compounds at 45°. His results at 30° are shown graphically in Fig. 22, the region *bMc* corresponding with the solid phase

$(NH_4)_2O.B_2O_3.2\frac{1}{2}H_2O$; the region *dPe* with the solid phase $(NH_4)_2O.5B_2O_3.8H_2O$; and the region *eBf* with boric acid, $B(OH)_3$..

J. J. Berzelius reported a basic salt *dihydrated tetra-ammonium diborate*, $2(NH_4)_2O.B_2O_3.2H_2O$, or $(NH_4)_4B_2O_5.2H_2O$, but there are doubts about the accuracy of the analysis. J. A. Arfvedson dissolved ammonium tetraborate in hot conc. aq. ammonia, and allowed the soln. to cool in a covered vessel, when crystals of the composition: $3(NH_4)_2O.4B_2O_3.3H_2O$, *ammonium octotritaborate*, separated out; he also found that 100 parts of crystalline boric acid absorbed 21 parts of ammonia, producing what was thought to be the enneahydrate, $3(NH_4)_2O.4B_2O_3.9H_2O$.

L. Gmelin slowly cooled a soln. of a " moderate " proportion of boric acid in hot aq. ammonia, and obtained tetragonal crystals. Analyses by L. Gmelin, E. Soubeiran, A. Laurent, and C. F. Rammelsberg correspond with **tetrahydrated ammonium tetraborate,** $(NH_4)_2O.2B_2O_3.4H_2O$, or $(NH_4)H(BO_2)_2.1\frac{1}{2}H_2O$. A. Atterberg's analysis agrees with the assumption that this salt is a pentahydrated tetraborate, $(NH_4)_2O.2B_2O_3.5H_2O$, and he considered this to be one of the only two ammonium borates whose existence has been established. This salt may have been U. Sborgi's hemipentahydrate, $(NH_4)_2O.2B_2O_3.2\frac{1}{2}H_2O$, with some entrained water. If so, the region of stability is fairly large, corresponding with *bcM*, Fig. 22. C. F. Rammelsberg found the axial ratios of the tetragonal crystals to be $a:c=1:0{\cdot}8283$. W. H. Miller described crystals of ammonium borate, but it is not clear what particular salt he measured. G. d'Achiardi also studied these crystals. L. Gmelin said that the crystals effloresce in air, lose ammonia, and form the octoborate; that 100 parts of cold water dissolve 8·3 parts of the salt, and that the soln. has an alkaline reaction, and evolves ammonia when heated. According to P. A. Favre and C. A. Valson, the sp. gr. of the *N*-soln. of this salt is 1·0678, and the volume increase per litre, attending the soln. of one eq. of the salt, is 10·2 c.c. According to M. Faraday, a neutral or slightly alkaline soln. of ammonium borate soon colours turmeric paper the red tint characteristic of boric acid, and the red tint is effected by ammonia, etc., as with the coloration produced by boric acid itself—*q.v.*

J. A. Arfvedson obtained a salt whose analysis corresponded with $2(NH_4)_2O.5B_2O_3.5H_2O$, but C. F. Rammelsberg believed this is probably a less pure form of the tetraborate. A. Schleisner reported *heptahydrated ammonium hexaborate*, $(NH_4)_2O.3B_2O_3.7H_2O$, to be formed by adding the calculated quantity of ammonia to a hot aq. soln. of boric acid. He added that the salt is formed only above 30°, and that it is very soluble in water. It is used for preparing hard and washable figures of plaster of Paris.

A. Atterberg mixed a hot soln. of boric acid with aq. ammonia in the proportion $NH_3:H_3BO_3=1:3{\cdot}5$, and obtained rhombic double pyramids of **octohydrated ammonium decaborate,** $(NH_4)_2O.5B_2O_3.8H_2O$, analogous to the corresponding potassium salt. The area *dPe* in U. Sborgi's diagram, Fig. 22, shows the range of stability of the salt at 30°. J. Schabus, and V. von Lang also measured the crystals, which have a positive double refraction. L. Gmelin obtained colourless, transparent, six-sided pyramids by saturating a hot conc. aq. soln. of ammonia with boric acid, and slowly cooling the mixture; he supposed the product to be *hexahydrated ammonium octoborate*, $(NH_4)_2O.4B_2O_3.6H_2O$, but it is probably a less pure form of the decaborate. C. F. Rammelsberg found the crystals to be rhombic bipyramids with axial ratios $a:b:c=0{\cdot}9827:1:0{\cdot}8201$. L. Gmelin said the crystals appear tasteless at first, but they afterwards excite a burning bitter taste. The salt is permanent in air, but when heated, it swells up and fuses, leaving behind glassy boric oxide which A. Laurent said still retains some ammonia very tenaciously. According to L. Gmelin, 100 parts of cold water dissolve nearly 12·5 parts of the salt, and the soln. gives off ammonia when boiled; the aq. soln. has an alkaline reaction. By treating the soln. with vanadium pentoxide, A. Ditte obtained ammonium trivanadate. The salt has also been studied by C. F. Wenzel, J. M. F. de Lassone, E. Soubeiran, and J. A. Arfvedson.

Analyses of the mineral *larderellite* occurring at the Tuscan lagoons, by the discoverer E. Bechi, and by J. A. Rose, correspond with *tetrahydrated ammonium* *octoborate*, $(NH_4)_2O.4B_2O_3.4H_2O$, or $(NH_4)_2B_8O_{13}.4H_2O$. The crystalline form of the rhombic plates has not been established. Larderellite is soluble in hot water, and, according to E. Bechi, the soln. deposits crystals of *enneahydrated ammonium dodecaborate*, $(NH_4)_2O.6B_2O_3.9H_2O$.

A. Dschawachoff[12] prepared rhombic crystals of **decahydrated hydrazine hexahydro-dodecaborate,** $(N_2H_4)_2(H_2B_4O_7)_3.10H_2O$, by adding boric acid to a 50 per cent. soln. of the base, and concentrating the soln. first on the water-bath, and then in a desiccator. The crystals readily effloresce, and when kept over sulphuric acid, pass into the pentahydrate, $(N_2H_4)_2(H_2B_4O_7)_3.5H_2O$, and at 100° they form the anhydrous salt, $(N_2H_4)_2(H_2B_4O_7)_3$. When heated to 250°–260°, they formed $(N_2H_4)_2(B_2O_3)_6$. Above 260°, the salt decomposes into boric acid and anhydrous hydrazine, N_2H_4.

§ 10. The Borates of Copper, Silver, and Gold

W. Hermann[1] found that a mixture of copper oxide and borax melts with difficulty and furnishes a blue glass. H. Hecht studied the effect of boric oxide on the colour of alkali silicate glasses coloured with cupric oxide. P. A. Bolley discussed the uses of the copper borates as pigments for painting. M. G. Levi and S. Castellani observed no signs of the formation of copper borates in the electrolysis of a soln. of boric acid in the cathode compartment, and of a soln. of a cupric salt in the anode compartment.

A. Rosenheim and F. Leyser made **cupric pentaborate**; and obtained the complex **hydrated tetrasodium tetracupric octodecaborate,** $2Na_2O.4CuO.9B_2O_3.38H_2O$, that is, $Na_4[Cu_4(B_4O_7)_6].50H_2O$. According to W. Guertler, brownish crystals, with a greenish surface shimmer, **cuprous tetraborate,** $Cu_6B_4O_9$, or $3Cu_2O.2B_2O_3$, are produced when cupric diborate, $Cu(BO_2)_2$, is heated until gas is developed, and washed with boiling water; when a mixture of three mols of cupric nitrate and two mols of boric oxide is heated until reduction is complete; and when cuprous hydroxide is evaporated with 3 to 5 eq. of boric acid, and heated; the homogeneous liquid cools to a reddish-yellow mass which is rapidly decomposed by water. F. P. le Roux said that when a fused glass $Cu_2O.2B_2O_3$ is rapidly cooled the colour is citron-yellow, if slowly cooled, orange; and if $Cu_2O.2B_2O_3$ is slowly cooled, it has an orange colour.

J. Tünnermann found borax precipitated a pale green cupric borate from a soln. of cupric sulphate; and different results are obtained according as the borax or cupric salt is in excess. The greater the proportion of the latter, the more basic the precipitate. The composition also depends on the conc. and temp. of the mixed soln. As a result quite a number of hydrated cupric borates have been reported, but there is nothing to show that any of them is a chemical individual.

According to H. Rose, cold conc. soln. of cupric sulphate and borax give a precipitate of $33CuO.20B_2O_3.33H_2O$, which when washed with cold water furnishes *dihydrated cupric diborate*, $CuO.B_2O_3.2H_2O$; and with hot conc. soln., the monohydrate is formed. A. Laurent obtained a similar hydrate, $2CuO.B_2O_3.1\frac{1}{2}H_2O$, by drying at 100°, the precipitate obtained by adding borax to a hot soln. of cupric sulphate. Expressing the mol. ratio $CuO : B_2O_3 : H_2O$, H. Rose obtained the salt 11 : 1 : 9 by washing the precipitate obtained by adding borax to a hot dil. soln. of cupric sulphate; by a long continued boiling with water, hydrated cupric oxide is finally obtained. E. Pasternack warmed a cold soln. of two parts of cupric sulphate and one of borax; the filtrate from the basic sulphate was dropped into an excess of a hot soln. of borax, and, on cooling, the compound 5 : 1 : 12 deposited. H. Rose obtained 4 : 1 : 3, by washing the 2 : 1 : 1 product with cold water. By washing the precipitate obtained by mixing equi-molar parts of cupric sulphate and borax in cold conc. soln., H. Rose obtained 9 : 5 : 9 which by washing with cold water gave 3 : 1 : 3; if hot soln. are employed, the precipitate is 11 : 5 : 11, and after washing with hot water, 11 : 4 : 11. H. Rose also obtained 5 : 2 : 5, by washing the precipitate obtained by mixing cold dil. soln. of cupric sulphate and borax.

W. Guertler evaporated a soln. of a mol of cupric nitrate with 2 mols of boric acid and fused the product in a platinum crucible at a temp. not exceeding 950°, the blue needle-like crystals have the composition of **cupric di- or metaborate,** $CuO.B_2O_3$, or $Cu(BO_2)_2$; he also obtained the same product by melting cupric oxide with a large excess of boric oxide, and slowly cooling the product; and A. Ditte, by the action of water on cupric tetraborate, CuB_4O_7. This product can also be obtained as a dark green glass. The blue doubly refracting needles have a sp. gr. 3·859±0·003, and the hardness of corundum. When heated to 875°±10°, oxygen is given off, and the weight becomes constant when 5·32 per cent. in weight has been expelled. H. Moissan found fluorine attacks copper borate vigorously at ordinary temp. and the mass becomes incandescent. Cold dil. mineral acids have no action; neither does dil. hydrofluoric acid attack the compound; conc. hydrofluoric acid has a slow solvent action. Sodium hydroxide and alkali sulphides have no action.; molten potassium hydrosulphate and molten alkali carbonates act slowly.

A. Ditte prepared crystals of **cupric tetraborate,** CuB_4O_7, by evaporating a soln. of cupric oxide or carbonate in one of boric acid sat. at 40°. E. Pasternack prepared hexahydrated **cupric tetramminotetraborate,** $CuB_4O_7.4NH_3.6H_2O$, by adding alcohol to an ammoniacal soln. of equi-molar parts of borax and cupric acetate, or by warming a soln. of a mol of cupric acetate and 2 mols of boric oxide in aq. ammonia, and filtering hot. On cooling, dark blue crystals are obtained which can be crystallized from aq. ammonia. They effloresce in air, smell of ammonia, and are decomposed when boiled with water, with the separation of cupric tetraborate.

J. Donau[2] found silver dissolves in fused borax, staining it yellow. J. Tünnermann noted the formation of a white precipitate when borax is added to soln. of silver nitrate. According to H. Rose, equi-molar and N-soln. of sodium borate and silver nitrate in the cold give a dirty yellow precipitate which when pressed contains $11Ag_2O.10B_2O_3.10H_2O$; and after washing with cold water, and drying contains $6Ag_2O.B_2O_3$. Cold conc. soln. of 2 mols of silver nitrate and one mol of borax give a precipitate containing $3Ag_2O.4B_2O_3$, and after washing, $4Ag_2O.5B_2O_3$. Boiling conc. soln. of the two salts precipitate silver oxide only; whilst very dil. soln. give the same precipitate. L. Joulin also found that an excess of borax precipitates **silver metaborate,** $AgBO_2$, from a conc. soln. of silver nitrate, but if the latter is in excess, or if the soln. be dil., silver oxide is precipitated. H. Rose found that potassium borate behaves like sodium borate; a conc. soln. of ammonium borate precipitates silver borate from a soln. of silver nitrate; with dil. soln. silver oxide alone is precipitated. As L. Vanino showed, the silver tetraborate first precipitated is more or less hydrolyzed according to the conc. of the soln. A. Laurent said that potassium hexaborate gave a white precipitate with soln. of silver nitrate. E. C. Franklin found silver borate is insoluble in liquid ammonia; and H. Hamers, that it is insoluble in ethyl acetate. R. Abegg and A. J. Cox found a litre of aq. soln. at 25° contains about 9·05 grms. of $AgBO_2$; and they also studied the hydrolyses of silver borate by water. *Gold borate* has not been prepared.

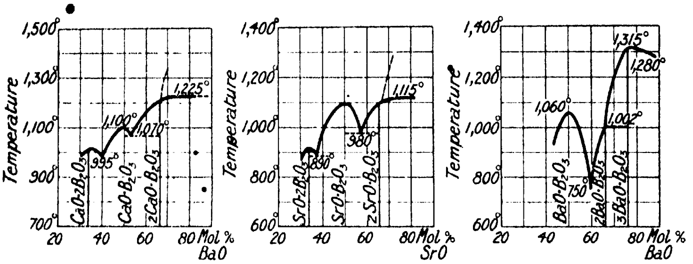
§ 11. The Borates of the Alkaline Earths

T. Bergman[1] prepared calcium, barium, and magnesium borates. He said:

> Depurated borax may be decomposed by boiling with lime; the acid forsakes the caustic fossil alkali to seize the lime, and produces a salt scarcely soluble. The same thing takes place within ponderous earth, and magnesia.

A. Ditte said that a boiling aq. soln. of borax does not decompose calcium carbonate, and C. Tissier, that calcium hydroxide but not calcium carbonate is soluble in a boiling aq. soln. of boric acid, that barium carbonate is not soluble in aq. soln. of boric acid; and that if a soluble calcium salt be boiled with an excess of an aq. soln. of boric acid, no precipitate occurs if enough borax be added to make the sodium of the borax eq. to the calcium of the calcium salt. J. H. van't Hoff studied the paragenesis of the calcium borates in natural salt deposits. For the formation of borate minerals, *vide* the occurrence of boron. A. Laurent studied the precipitates obtained by double decomposition of barium salts and borax; judging from the analysis, the products appear to be mixtures. L. B. Guyton de Morveau obtained a transparent glass by melting two parts of borax with one of barium oxide; and N. Tate melted barium sulphate with boric oxide at a high temp., but succeeded in displacing only a part of the sulphuric acid. Two layers were formed, a soln. of a little barium sulphate in boric acid above and a soln. of a little boric acid in barium sulphate below. Similar results were obtained with barium chloride and boric acid. W. Guertler partially explored the f.p. curves of fused mixtures of boric oxide with the alkaline earths, and obtained the results shown graphically in Figs. 23, 24, and 25. The calcium curve has maxima corresponding with $CaO.2B_2O_3$; $CaO.B_2O_3$; and $2CaO.B_2O_3$; the strontium-curve likewise with $SrO.2B_2O_3$; $SrO.B_2O_3$; and $2SrO.B_2O_3$. The curves were not continued to the left because of the non-crystallization of the glasses; and to the right, because the fusion temp. was outside the range of the apparatus employed. J. J. Berzelius noted that small proportions of barium oxide give transparent glasses when melted with boric acid, but crystalline masses are formed with higher proportions of baryta. There is nothing to show that calcium and strontium would not form orthoborates analogous to the barium compound; or that barium would not form a salt analogous to the calcium and strontium tetraborates. U. Sborgi has studied the ternary systems, $CaO-B_2O_3-H_2O$, and $BaO-B_2O_3-H_2O$, at 30°; the results with the lime system are represented graphically in Fig. 26, which shows but a portion of the triangular diagram, where *ab* denotes the solubility curve of calcium hydroxide; *bc*, of $CaO.B_2O_3.6H_2O$; *cd*, of $2CaO.3B_2O_3.9H_2O$; *de*, of $CaO.3B_2O_3.12H_2O$; and *ef*, of boric acid, $B(OH)_3$. Similarly, with the baryta system, he obtained as solid phases barium hydroxide $BaO.H_2O$ with the solubility



FIGS. 23-25. Freezing-point Curves of Binary Mixtures of Boric Oxide with Calcium, Strontium, or Barium Oxide.

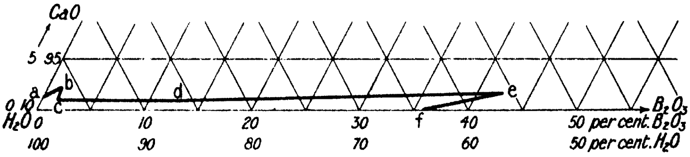


FIG. 26.—Solubility Curves in the Ternary System, $BaO—B_2O_3—H_2O$, at 30°.

curve *ab*, Fig. 27; $BaO.B_2O_3.4H_2O$, *bc*; $2BaO.3B_2O_3.6H_2O$, *cd*; $BaO.3B_2O_3.7H_2O$, *de*; and boric acid, $B(OH)_3$, *ef*.

L. Ouvrard claimed to have made transparent prismatic crystals of **calcium orthoborate,** $3CaO.B_2O_3$, or $Ca_3(BO_3)_2$, by melting at a red heat the eq. quantities of boric oxide and calcium oxide or carbonate with a flux of calcium chloride, or bromide or of potassium hydrofluoride free from potassium chloride. The cold mass was digested with cold water and then with dil. acetic acid. The crystals become opaque when boiled with water; and they are very soluble in dil. acids. The corresponding **strontium orthoborate,** $3SrO.B_2O_3$, or $Sr_3(BO_3)_2$, was prepared in a similar manner, and it was found to be less readily attacked by water than with the calcium salt; similar remarks apply to **barium orthoborate,** $3BaO.B_2O_3$, or $Ba_3(BO_3)_2$. The last-named compound was also prepared by W. Guertler, and found to melt at about 1315° (Fig. 25).

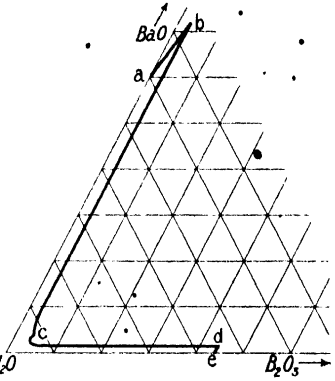

Fig. 27.—Solubility Curves in the Ternary System, $CaO-B_2O_3-H_2O$, at 30°.

L. Ouvrard melted a mol of boric oxide, 0·5 mol of calcium oxide, and 2 mols of calcium chloride in the presence of 50 per cent. of sodium or potassium chloride, and extracted the cold mass with water; 2 mols each of calcium oxide and bromide, and one of boric oxide gave similar results. Transparent, doubly refracting tabular crystals were obtained of **dicalcium diborate,** $2CaO.B_2O_3$, or $Ca_2B_2O_5$, very resistant towards cold water, but soluble in dil. acids. H. S. Roberts gave 1304° for the m.p. L. Ouvrard prepared **distrontium diborate,** $2SrO.B_2O_3$, or $Sr_2B_2O_5$, and **dibarium diborate,** $Ba_2B_2O_5$, in a similar manner. The prismatic crystals of the strontium compound are readily soluble in dil. acids, and form the tetrahydrated metaborate when treated with water. W. Guertler prepared these three salts—Figs. 23 to 25—and found them to melt with decomposition respectively at 1225°, 1115°, and 1002°. A. Ditte claimed to have made tabular and columnar crystals of *tristrontium tetraborate*, $3SrO.2B_2O_3$, by heating equi-molar parts of strontia and boric oxide in a carbon crucible to bright redness. The molten portion crystallized on cooling. The chemical individuality of the product has not been confirmed.

A. Ditte reported **calcium metaborate or diborate,** $CaO.B_2O_3$, or $Ca(BO_2)_2$, to be formed by fusing the precipitate obtained by adding borax to a soluble calcium salt, with a mixture of potassium and sodium chlorides and less than 25 per cent. of calcium chloride; and H. le Chatelier also prepared the crystals by melting together equi-molar proportions of the components. The crystals were washed with water and dil. acetic acid. As L. Vanino showed, the tetraborate first precipitated is hydrolyzed, thus $CaB_4O_7+3H_2O \rightleftharpoons Ca(BO_2)_2+2H_3BO_3$; or even $CaB_4O_7+7H_2O \rightleftharpoons Ca(OH)_2+4H_3BO_3$ crystals form transparent needles, prisms, or plates, which, according to E. Mallard, belong to the rhombic system, and have axial ratios $a:b:c=0.539:1:0.372$. The double refraction is negative, and the indices of refraction for Na-light are $\mu_\alpha=1.540$; $\mu_\beta=1.656$; and $\mu_\gamma=1.682$. A. Ditte found that the crystals are insoluble in water, in aq. soln. of the alkali chlorides, or in boiling conc. acetic acid; but they are soluble in hot or cold soln. of ammonia salts—especially the nitrate; and readily soluble at 50° in dil. mineral acids. W. Guertler prepared the same compound melting at 1100° (Fig. 23). L. Ouvrard prepared **strontium metaborate or diborate,** $SrO.B_2O_3$, and found that water converted it into the dihydrate. W. Guertler's preparation melted at about 1100° (Fig. 24). L. Ouvrard made **barium metaborate or diborate,** $BaO.B_2O_3$, in a similar manner to the strontium compound; R. Benedikt made it by melting sodium metaborate with an eq. amount of barium chloride, and extracting the mass with water; and W. Guertler made it by fusing together the components. The acicular crystals melt at 1060° (Fig. 25). G. Tammann found the heats of soln. of calcium and strontium metaborates in N-HCl, to be respectively 161 and 141 cals. per gram for the crystals, and 211 and 175 cals. per gram for the glasses; hence, the heats of crystallization are respectively 50 and 34 cals. per gram. The sp. hts. of the crystals were respectively 0·222 and 0·176, and of the glasses 0·218 and 0·175.

A. Ditte mixed the precipitate, obtained by adding borax to a soln. of a calcium salt and washing, with an excess of a soln. of calcium hydroxide; crystals are gradually formed which he regarded as heptahydrated calcium diborate, but which J. H. van't Hoff and W. Meyerhoffer showed to be **hexahydrated calcium diborate,** $Ca(BO_2)_2.6H_2O$. W. Meyerhoffer made the same salt by the action of boric acid on calcium chloride in an aq. soln. of potassium hydroxide. The conditions of stability at 30° were worked out by U. Sborgi, Fig. 27. When a soln. of calcium hydroxide is gradually added to an eq. quantity of a soln. of boric acid at 60°–70°, an amorphous precipitate is formed approximating to $CaO.B_2O_3.4H_2O$; but after shaking the mixture for several days, the precipitate becomes crystalline and has the composition $CaO.B_2O_3.6H_2O$. Two-thirds of the water is lost at 105°, and the remainder at a red heat; and it is hence inferred that 4 mols. of water are associated differently from the remaining two; and this idea is expressed by regarding the salt as **tetrahydrated calcium tetrahydroxyorthoborate,** $Ca[O.B(OH)_2]_2.4H_2O$. According to A. Ditte, the crystals are six-sided prisms, or hexagonal plates. They are rapidly dehydrated at 80°, at 10° a litre of water dissolves 2 grms. of the salt, and the soln. has an alkaline reaction. The salt is not decomposed by atm. carbon dioxide. According to J. H. van't Hoff, U. Behn, and W. Meyerhoffer, when the hexahydrate is heated with water below 50°, long rectangular crystals are formed of an unstable **tetrahydrated α-calcium diborate,** $Ca(BO_2)_2.4H_2O$, which has a transition temp. at 24° when it passes into the hexahydrate. When the α-salt is heated it contracts and passes into a stable β-form, namely, **tetrahydrated β-calcium diborate.** This change is greatly accelerated if sodium chloride be present in the soln.—with a 10 per cent. soln. of sodium chloride it occurs at 40°. The crystals of the hexahydrate were also found to become opaque when warmed, and to pass by reversible transformation at 45·5° into an unstable **dihydrated calcium diborate,** $Ca(BO_2)_2.2H_2O$. H. Rose obtained this salt by treating equi-molar parts of cold soln. of sodium metaborate and calcium chloride; pressing the precipitate, and drying at 100°—the analysis agreed with $11CaO.10B_2O_3.18H_2O$. At 200°, the salt still retained a mol of water, and not all was expelled at 300°. The salt absorbs carbon dioxide when it is being washed, and the product is then poorer in water. The precipitates which H. Rose obtained under similar conditions with barium chloride were regarded as *barium borocarbonate*, $3(BaO.B_2O_3.H_2O)CO_2$. or $BaO.B_2O_3.CO_2.7H_2O$.

A. Ditte prepared **pentahydrated strontium diborate,** $Sr(BO_2)_2.5H_2O$, by a process similar to the one he employed for his heptahydrated calcium diborate. A litre of water at 10° dissolves 2·3 grms. of the prismatic crystals without decomposition. L. Ouvrard obtained **tetrahydrated strontium diborate,** $Sr(BO_2)_2.4H_2O$, by the action of water on his $2SrO.B_2O_3$; and prismatic crystals of **dihydrated strontium diborate,** $Sr(BO_2)_2.2H_2O$, by the action of cold water on his $SrO.B_2O_3$. The crystals become matt on exposure to air, and, according to E. Mallard, they belong to the rhombic system, and have a sp. gr. of 3·34. J. J. Berzelius prepared a hydrated barium diborate, $BaO.B_2O_3.nH_2O$, by adding potassium diborate to a soln. of barium chloride. H. N. Morse with W. M. Burton and D. W. Horn found that when the precipitate obtained with an alcoholic soln. of boric acid is treated with baryta water, it has a constant composition $BaO : B_2O_3=1:1$, and can be used for the gravimetric determination of boric acid in the presence of carbonates; L. C. Jones showed that the process is not accurate in aq. soln. A. Ditte prepared **penta-**

hydrated barium diborate, $Ba(BO_2)_2.5H_2O$, by the process he employed for the strontium salt; the crystals lose their water when heated and fuse to a transparent glass at a red heat. L. Ouvrard obtained **tetrahydrated barium diborate**, $Ba(BO_2)_2.4H_2O$, by a process similar to that which he employed for the strontium salt. A. Atterberg also prepared the same salt by mixing warm soln. of two mols of barium hydroxide and one mol of boric acid, and allowing the mixture to stand for some time. The voluminous precipitate furnishes prismatic crystals which do not melt in their own water of crystallization. The dehydrated salt melts at a white heat, and cools to a mass of needle-like crystals. U. Sborgi explored the region of stability of the tetrahydrate at 30°, Fig. 26. By using an excess of barium hydroxide in a boiling soln., A. Atterberg obtained crystals of **dihydrated barium diborate**, $Ba(BO_2)_2.2H_2O$; L. Ouvrard obtained the dihydrate by a similar process to that used for the strontium salt. A. Laurent dropped a soln. of the octoborate $Na_2O.4B_2O_3$ into a warm soln. of barium nitrate, and obtained what he regarded as *decahydrated barium diborate*, $BaO.B_2O_3.10H_2O$.

G. vom Rath applied the term *pandermite* to a hydrated calcium borate which occurs in a field covering about 20 sq. miles near the port of Panderma, on the Black Sea side of Asia Minor; the field embraces the villages of Sultan, Thair, Yildiz, and Omerly. It is situated in a basin surrounded by volcanic hills and the presence of hot mineral springs in various parts testifies to the volcanic influences at work in the formation of this mineral. Pandermite exists in closely packed snow-white nodules of irregular shape and size, in an enormous bed of grey-coloured gypsum, covered with several feet of clay. The chemical composition approaches that of colemanite, but the latter exfoliates and decrepitates when heated, while pandermite sinters together and fuses to a transparent mass. The general appearance of pandermite recalls that of fine-grained marble. Analyses and reports have been made by K. Kraut, G. Linck, A. Kenngott, M. Schlüter, A. Scheuer, J. E. Whitfield, F. Pisani, G. vom Rath, etc. The range is B_2O_3, 40·90 to 48·63 per cent.; CaO, 27·22 to 32·16 per cent.; water, 18·06 to 19·40 per cent.; and in addition, a sample contained:

MgO	$CaCo_3$	NaCl	$MgCl_2$	Fe_2O_3	H_2SO_4	SiO_2
0·24	6·82	0·44	0·09	0·60	2·11	2·47 per cent.

Pandermite is sold on a basis of 44 per cent. B_2O_3—sometimes as *Turkish boracite*. E. S. Dana, J. E. Whitfield, and E. S. Larsen considered pandermite to belong to the same mineral species as *princeite*, which occurs, associated with serpentine, in compact nodules and in chalky powder consisting of minute rhombic crystals near Chetko in Oregon. The analyses of B. Silliman, and A. W. Chase correspond with $3CaO.4B_2O_3.6H_2O$; and this in turn is not very different from the *cryptomorphite* of H. How, except that the latter contains some soda. C. F. Rammelsberg represented the composition of pandermite by $Ca_3B_8O_{15}.5H_2O$, or $3CaO.4B_2O_3.5H_2O$; G. vom Rath, $2CaO.3B_2O_3.3H_2O$; B. Silliman, H. Gilbert, G. Linck, and W. Meyerhoffer and J. H. van't Hoff, $Ca_8B_{20}O_{38}.nH_2O$, where the ratio $CaO:B_2O_3=4:5$. The best representative formula is enneahydrated **tetracalcium decaborate**, $4CaO.5B_2O_3.9H_2O$. According to J. H. van't Hoff, pandermite is synthesized by boiling boronatrocalcite with a sat. soln. of sodium and potassium chlorides—the temp. approximates 110°. When the product is allowed to stand a few days with its own mother liquid, well-developed crystals are produced. G. Linck found that the crystals of pandermite belong to the monoclinic system with $a:b:c=0·555:1:$—, and β about 70°. The optical axial angle $2V_a$ is about 35°; and the cleavage parallel to (001) is good, while that parallel to (110) is not so good. The index of refraction is 1·592. E. S. Larsen gave $\alpha=1·582$, $\beta=1·592$, and γ less than 1·606. G. Linck gave 2·433 for the sp. gr.

H. Rose prepared what he regarded as *heptahydrated tristrontium decaborate*, $3SrO.5B_2O_3.7H_2O$, by mixing equi-molar soln. of borax and strontium chloride in the cold—if the soln. be heated, less boric oxide is present in the product. The pressed *precipitate dried at 100° retains 7 mols of water, 3 of which are lost at 200°.* A. Ditte prepared long silky needles of anhydrous **dicalcium hexaborate,** or *calcium sesquiborate,* $2CaO.3B_2O_3$, or $Ca_2B_6O_{11}$, by fusing calcium oxide with a small excess of boric oxide in the presence of 50 per cent. of a mixture of sodium and potassium chlorides; and also by melting some calcium borates with alkali chlorides. He also made six-sided prisms of **dibarium hexaborate,** or *barium sesquiborate,* $2BaO.3B_2O_3$, or $Ba_2B_6O_{11}$, in a similar way. The salt is easily soluble in warm dil. acids. The mineral *colemanite* approaches **pentahydrated dicalcium hexaborate,** $2CaO.3B_2O_3.5H_2O$, or $Ca_2B_6O_{11}.5H_2O$, in composition. It was named after W. T. Coleman, one of the founders of the Californian borax industry. The chief sources of supply are the mines in Death Valley, California, and at Lang, near Los Angeles. The mineral has the appearance of calcspar, and is sometimes called *borspar;* its colour varies from white to yellowish-white, or grey; its hardness is 3½ to 5, and although it pulverizes easily, the sharp edges of the crystals rapidly wear the pulverizing plant. The ore as mined runs 30 to 35 per cent. B_2O_3. A selected sample from Lang, according to F. M. Dupont, had the analysis:

B_2O_3	CaO	Al_2O_3	Fe_2O_3	MgO	CO_2	SiO_2	H_2O
31·10	23·74	1·27	1·32	2·36	5·14	13·97	16·10

Analyses have also been made by J. T. Evans, and J. E. Whitfield. According to J. H. van't Hoff, the naturally occurring calcium borates lie between the di- and hexaborates, and borates containing CaO : B_2O_3 in the same ratio as in colemanite, are obtained by adding boric acid to the diborates, or removing boric acid from the higher borates. For example, colemanite is synthesized in a crystalline form by heating to 70° a mixture of 140 c.c. of water with 50 grms. of sodium chloride and 4 grms. of boronatrocalcite, together with 0·4 grm. of boric acid to avoid the production of pandermite. H. Rose made a hydrated borate by adding an excess of calcium chloride to a soln. of borax; after washing it contained CaO : B_2O_3 in the ratio 2 : 3, and when dried at 100° retained 3½ to 5 mols of water; and at 300°, 1½ mols. The sp. gr. of colemanite so prepared is 2·43. J. T. Evans found 2·428, and G. vom Rath gave 2·417 for the sp. gr. of native borate; G. vom Rath found the monoclinic prisms of the mineral have the axial ratio $a : b : c = 0{\cdot}7769 : 1 : 0{\cdot}5416$, and $\beta = 110° 17'$; A. W. Jackson gave 0·7748 : 1 : 0·5410, and $\beta = 69° 50' 45''$; and A. S. Eakle, 0·7768 : 1 : 0·5430, and $\beta = 110° 7'$. W. W. Coblentz found colemanite to be unusually opaque to ultra-red radiations, and it is almost opaque beyond 3μ. This opacity is characteristic of the borates. The water bands at $1{\cdot}5\mu$, 2μ, and 3μ are almost obliterated. The reflecting power is very low. There are maxima at $7{\cdot}3\mu$, $(7{\cdot}6\mu)$, $9{\cdot}4\mu$, $10{\cdot}6\mu$, and $11{\cdot}2\mu$. A. S. Eakle described a borate from Lang, Los Angeles, which agrees with colemanite from Death Valley, Inyo, and Calico district, San Bernardino, in its general chemical and physical properties, but "in its optical properties it is somewhat different so that the name *neocolemanite* is proposed to distinguish it as a variety from colemanite." A. Hutchinson, however, showed that the two minerals have the same optical and crystallographic properties if the neocolemanite crystals be rotated through 180° about the normal to the cleavage plane (001). The double refraction is positive; and the indices of refraction, according to A. Mülheims, are:

	B-line	*C*-line	*D*-line	*E*-line	*F*-line
α	1·58230	1·58345	1·58626	1·58952	1·59214
β	1·58807	1·58922	1·59202	1·59531	1·59810
γ	1·60978	1·61100	1·61398	1·61762	1·62044

According to W. Meyerhoffer and J. H. van't Hoff, when hexahydrated calcium diborate, $Ca(BO_2)_2.6H_2O$, is heated at 100° with a 3 per cent. soln. of boric acid, it is converted into **heptahydrated dicalcium hexaborate,** $Ca_2B_6O_{11}.7H_2O$, which forms long rectangular crystals possibly identical with the hexahydrate reported by K. Kraut in 1862 as being obtained by the action of water on boronatrocalcite. It is distinguished from colemanite in the proportion of water it contains, and, regarded as a mineral, it is called *meyerhofferite*. W. T. Schaller found small transparent colourless crystals of meyerhofferite in the colemanite deposit of Death Valley (Cal.). The triclinic crystals had the axial ratios $a:b:c=0{\cdot}7923:1:0{\cdot}7750$, and $\alpha=89^\circ\ 32'$, $\beta=78^\circ\ 19'$, $\gamma=86^\circ\ 52'$; the sp. gr. was 2·120; the hardness 2; and refractive indices $\alpha=1{\cdot}500$, $\beta=1{\cdot}535$, $\gamma=1{\cdot}560$. The mineral fuses without decrepitation, but with intumescence, forming an opaque white enamel. A. Atterberg also made **heptahydrated dibarium hexaborate,** $Ba_2B_6O_{11}.7H_2O$, as an amorphous precipitate by adding boric acid to an excess of an aq. soln. of barium hydroxide. It loses 4 mols of water at 100°, and the remainder on further heating; it melts at a red heat without swelling. W. Meyerhoffer and J. H. van't Hoff also made **enneahydrated calcium hexaborate,** $Ca_2B_6O_{11}.9H_2O$, by heating hydrated calcium diborate with the requisite amount of an aq. soln. of boric acid; or by the action of water on octohydrated calcium hexaborate, $Ca_3B_6O_{11}.8H_2O$, at ordinary temp. It forms crystals resembling augite. The mineral *inyoite* is **tridecahydrated calcium hexaborate,** $CaB_6O_{10}.13H_2O$. Crystals found by W. T. Schaller in the colemanite deposit of Death Valley (Inyo Co., Cal.); and by E. Poitevin and H. U. Ellsworth in the Whitehead gypsum quarry, Hellsborough (New Brunswick, Canada). The monoclinic crystals of inyoite have the axial ratios $a:b:c=0{\cdot}94:1:0{\cdot}67$, and $\beta=62^\circ\ 30'$; the sp. gr. is 1·875; hardness 2; and refractive indices $\alpha=1{\cdot}495$, $\beta=1{\cdot}51$, and $\gamma=1{\cdot}520$. Inyoite decrepitates and fuses with intumescence before the blowpipe flame.

H. Rose prepared **enneahydrated tricalcium decaborate,** $Ca_3B_{10}O_{18}.9H_2O$, or $3CaO.5B_2O_3.9H_2O$, by precipitation from a cold soln. of calcium chloride with borax in equi-molar proportions. The exact proportions of water in H. Rose's product was not definitely determined, but J. H. van't Hoff also made needle-like crystals of the enneahydrate by heating boronatrocalcite with a soln. of borax, when $2CaO.3B_2O_3.7H_2O$ is formed at an intermediate stage of the reaction. H. Rose also made **heptahydrated tristrontium decaborate,** $Sr_3B_{10}O_{18}.7H_2O$. If precipitated from a hot soln., the product contains a smaller proportion of boric oxide. H. Rose made **hexahydrated tribarium decaborate,** $3BaO.5B_2O_3.6H_2O$. H. Rose found the strontium salt retains 3 mols of water at 200°, J. J. Berzelius said that 100 parts of cold water dissolve one part of the barium salt; and on cooling the hot soln. a white powder is deposited; carbon dioxide precipitates barium carbonate from the soln. According to R. H. Brett, and H. W. F. Wackenroder the salt dissolves readily in cold aq. soln. of ammonium chloride or nitrate; and, according to H. Rose, in a soln. of barium chloride. L. C. Jones found barium borate is decomposed by carbon dioxide in aq. or alcoholic soln.

A. Ditte prepared crystalline plates of anhydrous **calcium tetraborate,** CaB_4O_7, or $CaO.2B_2O_3$, by melting calcium oxide with an excess of boric acid and a mixture of sodium and potassium chlorides. B. Blount and W. Guertler (Fig. 23) made this compound by fusing the constituents together, and they added that it is decomposed by water. A. Ditte and H. le Chatelier also made fine needles of anhydrous **strontium tetraborate,** $SrO.2B_2O_3$, by boiling strontium carbonate with boric acid; by precipitating a soln. of strontium nitrate with borax; and by the method used for the calcium salt. W. Guertler found that if strontia is melted with an excess of boric oxide, two layers are formed: the upper layer contains but little strontia, but when the lower glassy layer is heated some days it forms crystals of this salt from which the excess of boric acid is removed by water—*vide* Fig. 24.[9] A. Ditte made anhydrous **barium tetraborate,** BaB_4O_7, by a process similar to that employed for the strontium salt. All these borates are soluble in dil. nitric acid. J. J. Berzelius noted that when calcium chloride is added to a warm soln. of borax, the precipitate redissolves (on cooling), but if an excess of borax be used, the precipitate is permanent. A. Ditte prepared pentahydrated calcium tetraborate, $CaB_4O_7.5H_2O$, by adding lime water to an aq. soln. of boric acid sat. at 40° and warming the filtered soln. to 70°; the precipitate which is formed redissolves as the soln. cools; but if most of the hot mother liquid be poured off, and the precipitate and the mother liquid be allowed to stand for some months, needle-like crystals of this salt are formed. They are decomposed by much water into the diborate. The bechilite of E. Bechi, and the hayesine of D. Forbes were considered to be tetrahydrates, but J. H. van't Hoff could not make them artificially. J. Tünnermann believed the air-dried precipitate produced by adding borax to a soln. of calcium nitrate is a monohydrate, $CaO.2B_2O_3.H_2O$; L. R. Lecanu obtained what he regarded as a tetrahydrate, $CaO.2B_2O_3.4H_2O$, by the action of boiling water on boronatrocalcite; O. Popp obtained what he regarded as the octohydrate, $CaO.2B_2O_3.8H_2O$, by drying in air the product obtained by heating an aq. soln. of boric acid with calcium carbonate. E. Bechi found crusts of tetrahydrated calcium tetraborate are deposited from the Tuscan springs, and, when regarded as a mineral, the salt is called *bechilite;* and the *hayesine* of D. Forbes, deposited from the hot springs of Banos del Toro, Cordilleras (Coquimbo), is possibly the same. The *borocalcite* found by A. A. Hayes at Iquique (Peru) was said to be a hexahydrate, $CaO.2B_2O_3.6H_2O$. J. H. van't Hoff said that all attempts to prepare *borocalcite*, $CaO.2B_2O_3,4H_2O$, from natural sources have been unsuccessful; various specimens from collections have been shown to be boronatrocalcite, pandermite, etc. Experiments to prepare it have also been without the desired result. An aq. soln. of lime and boric acid, kept at 40° for three weeks, deposits a substance of the approximate composition demanded by the formula; it is really, however, a mixture of calcium hexaborate, $CaO.3B_2O_3.4H_2O$, and dicalcium hexaborate, $2CaO.3B_2O_3.9H_2O$. At 83°, however, this soln. deposits, after two months, colemanite; this is the best method of obtaining artificial colemanite. Borocalcite, if capable of existence, is therefore very difficult to prepare. J. H. van't Hoff also studied the limits of formation of colemanite, pandermite, boronatrocalcite, and the tetrahydrate, $NaCaB_5O_9, 4H_2O$, and represented his results graphically in conjunction with those of sylvine, borax, calcium chloride, etc. The rule that the difficulty of forming artificial minerals increases from the chlorides to the sulphates and to the borates is given a quantitative significance, in which the idea of "mean valence" is introduced. "Mean valence" is a quotient of two totals; the values for Na, K, Cl are 1; Ca, Mg, SO_4, 2: B_2O_3, 6, and H_2O, 4, in the numerator, those in the denominator being Na, K, Cl, Ca, Mg, SO_4, 1; B_2O_3, 2; and H_2O; thus for ascharite, $MgHBO_3$ or $2MgO.B_2O_3.H_2O = (4+6+4)/(2+2+3) = 2$. A. Laurent and A. Ditte obtained **tetrahydrated strontium tetraborate,** $SrO.2B_2O_3.4H_2O$, by double decomposition between aq. soln. of borax and strontium chloride. R. H. Brett said that the precipitate is soluble in soln. of ammonium salts, and that 100 parts of water dissolve 0·77 part of the salt. It is thought that the product obtained by J. J. Berzelius, and C. G. Gmelin, and J. Tünnermann by the action of an excess of borax on a soln. of barium chloride is hydrated barium tetraborate salt. According to L. W. Kölreuter, it behaves like barium carbonate towards alkali sulphates.

According to A. Ditte, if calcspar be boiled with a sat. soln. of boric acid, **tetrahydrated calcium hexaborate,** $CaO.3B_2O_3.4H_2O$, or $CaB_6O_{10}.4H_2O$, is formed as a crystalline crust which loses all its water at 200°, and melts to a glassy mass at 400°. W. Meyerhoffer and J. H. van't Hoff found that the **dodecahydrated calcium hexaborate,** $CaB_6O_{10}.12H_2O$, is formed by shaking the above hexahydrate with boric acid in cold aq. soln.; the conversion is complete in about twenty-four hours. This hydrate is unstable and changes at the ordinary temp. into the **octohydrated calcium hexaborate,** $CaB_6O_{10}.8H_2O$, which forms doubly refracting leaflets and slowly undergoes degradation to A. Ditte's tetrahydrate. A. Ditte made **strontium hexaborate,** $SrO.3B_2O_3$, by the action of borax on an excess of strontium oxide. According to A. Atterberg, if an aq. soln. of baryta-water be dropped into an excess of an aq. soln. of boric acid, a precipitate nearly corresponding with *hexahydrated barium hexaborate*, $BaO.3B_2O_3.6H_2O$, is formed, but since the composition varies a little, the product is thought to be a mixture.

A. Laurent boiled milk of lime with an excess of boric acid, and obtained a white precipitate whose analysis corresponded with **enneahydrated calcium octoborate,**

$CaO.4B_2O_3.9H_2O$; and A. Ditte obtained **dodecahydrated calcium octoborate,** $CaO.4B_2O_3.12H_2O$, by treating a soln. of boric acid, sat. at 40°, with milk of lime, and evaporating the filtered soln. slowly at ordinary temp. The product decomposes at 70° into water, boric acid, and a little tetraborate which in turn decomposes into the diborate. A. Ditte also prepared **heptahydrated strontium octoborate,** $SrO.4B_2O_3.7H_2O$, **dodecahydrated strontium octoborate,** $SrO.4B_2O_3.12H_2O$; and also **dodecahydrated barium octoborate,** $BaO.4B_2O_3.12H_2O$. A. Laurent assumed that he made *barium, strontium, and calcium dodecaborates* as precipitates by adding ammonium or an alkali dodecaborate to a soln. of the corresponding salt.

J. J. Berzelius found calcium oxide dissolves in fused borax, forming a clear glass, which on cooling furnishes a crystalline mass if a large proportion of lime is present; if otherwise, a glass is formed. The mineral *boronatrocalcite* is a sodium calcium borate also called *ulexite* after G. L. Ulex,[2] who first gave a correct analysis. It occurs in the dry plains of the provinces of Tarapaca, Atacama, Ascotan, Maricunga, and Copiapó in Chile and Peru, as in white roundish masses mixed with aluminium, magnesium, calcium, and sodium sulphates, sodium chlorides, etc. These masses are locally called *tiza, cotton-balls, tincalcite,* or *borax-lime.* It also occurs in the desert regions in zones or layers alternating with strata of salty earth, and also on the West African coast; in Nova Scotia; etc. Analyses have been published by G. L. Ulex, C. F. Rammelsberg, A. Dick, K. Kraut, F. W. Helbig, G. Lunge, M. Kletzinsky, T. L. Phipson, A. Salvétat, H. How, T. L. Walker, etc. These analyses range from 34·71 to 49·5 per cent. of boric oxide; 12·69 to 15·9, calcium oxide; 5·42 to 11·95, sodium oxide; 0·5 to 1·0, potassium oxide; 25·80 to 37·40, water; 0·81 to 2·65, sodium chloride; magnesia up to about 0·5; sulphate up to about 1·5 per cent.; and earthy matters and sand up to about 5 per cent. F. M. Dupont gives the following analysis of a sample from Ascotan, and J. E. Whitfield of a sample from Rhodes' Marsh, Esmeralda County, Nevada:

	B_2O_3	H_2O	Na_2O	CaO	MgO	SiO_2	Cl	SO_3
Ascotan	38·04	19·86	15·91	12·34	0·37	4·95	9·64	0·84
Rhodes' Marsh	43·20	29·46	10·20	14·52	—	0·04	2·38	0·28

and in sample A, 0·24 per cent. of ferric oxide and alumina, and in sample B, 0·44 per cent. of K_2O. The difficulties in the determination of boric oxide left the composition of the mineral for some time in doubt; and it was thought that the contained soda might be present as an impurity. A. Raimondi stated that all Peruvian calcium borates contain some soda. Different formulæ have been assigned to the mineral; K. Kraut gave $(Na_2O.2B_2O_3)(CaO.3B_2O_3).15H_2O$, or $Na_2CaB_{10}O_{17}.15H_2O$; C. F. Rammelsberg, $(Na_4B_6O_{11})(Ca_2B_6O_{11})_2.28H_2O$; J. E. Whitfield gave $NaCaB_5O_9.6H_2O$; and L. Darapsky, and H. Gilbert, $NaCaB_5O_9.8H_2O$, *i.e.* $Na_2O.2CaO.5B_2O_3.16H_2O$. The analyses of artificial boronatrocalcite agree with the last-named formula, **hexadecahydrated sodium dicalcium decaborate.**

T. L. Walker measured the loss which occurs when the ulexite is heated for 24 hrs. at different temp. up to 355°; he found that the first 12 mols of water are given off very readily and in proportion to the rise of temp., except the fifth mol, which appears to be more firmly held; the last four mols are held more closely and are slowly driven off. Of these, the last is held most firmly, and is given off between 355° and red heat. The dehydration curve is illustrated in Fig. 28.

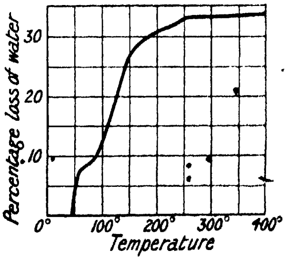

FIG. 28.—Dehydration Curve of Ulexite, $Na_2O.2CaO.5B_2O_3.16H_2O$.

H. How's *cryptomorphite* occurring in minute plates, has an analysis corresponding with $Na_2O.3CaO.9B_2O_3.12H_2O$; it is said to lose much of its water when exposed to air. It is probably a mixture. J. E. Reynolds obtained a massive white mineral with a fine fibrous structure, of hardness 1, and sp. gr. 1·65, from Tarapaca, Peru. Analyses agreed with the formula $2Na_2O.2CaO.6B_2O_3.15H_2O$, or $Na_2CaB_6O_{11}.7\frac{1}{2}H_2O$, and it was named *franklandite*. J. H. van't Hoff said that the analytical data correspond with an impure boronatrocalcite, and his attempts to obtain the product artificially were unsuccessful; when a mixture of boronatrocalcite and borax is heated to 60°, pentahydrated sodium tetraborate appears at 60°, and at 63°, the boronatrocalcite loses water with the formation of **octohydrated sodium dicalcium decaborate,** $Na_2O.2CaO.5B_2O_3.8H_2O$, or $NaCaB_5O_9.4H_2O$. Consequently, the formation of colemanite from boronatrocalcite at about 65° according to the equation: $2NaCaB_5O_9.8H_2O{=}Na_2B_4O_7.5H_2O{+}Ca_2B_6O_{11}.5H_2O{+}6H_2O$, is possible only when superheating of the boronatrocalcite takes place. This implies that the upper temp. limit for the existence of boronatrocalcite is lower than that previously recorded, and dilatometer experiments indicate that this limit is below 60°. In presence of sodium chloride, borax, potassium chloride and glaserite, decomposition of boronatrocalcite was found to take place at 51°.

A. B. de Schulten prepared boronatrocalcite by the action of an excess of a cold sat. soln. of borax on calcium chloride; the amorphous precipitate is transformed in 5–30 days into a mass of fine crystals. J. H. van't Hoff made it by mixing 110 grms. of hexahydrated calcium diborate, 40 grms. of boric acid, 100 grms. of borax, 450 grms. of calcium chloride, and $2\frac{1}{2}$ litres of water. The mixture is seeded with boronatrocalcite, and in a few days, the crystals are filtered off; washed successively with water, 75 per cent. alcohol, and ordinary alcohol; and then dried. W. Foshag and others assume that boronatrocalcite is formed in nature by the action of soln. of boric acid and sodium salts on marble; J. H. van't Hoff studied the paragenesis of the sodium calcium borates in the formation of salt deposits.

Although boronatrocalcite occurs in microscopically fine crystals—needles and plates—of snow-white colour, exact crystallographic data are not available. H. Buttgenbach has made some measurements. A. des Cloizeaux examined the corrosion figures. H. How gave 1·65 for the sp. gr. of the mineral; and A. B. de Schulten, 1·955 at 15° for the artificial compound. The compound loses its water of crystallization when heated; and melts at a red heat. H. Buttgenbach said that the crystals have a positive double refraction, while those of borocalcite are sometimes negative. Cold water extracts some soda from the mineral, but even boiling water (1 : 40) does not remove the soda completely, and L. R. Lecanu, and J. H. van't Hoff obtained crystals of tetrahydrated calcium tetraborate, $CaO.2B_2O_3.4H_2O$, from the hot aq. soln., while K. Kraut obtained $2CaO.3B_2O_3.6H_2O$. According to J. H. van't Hoff, the transformation of boronatrocalcite into the tetrahydrate—pandermite—proceeds much faster in porcelain than in glass vessels. With a boiling soln. of ammonium chloride, boronatrocalcite gives off ammonia.

§ 12. The Borates of Beryllium, Magnesium, Zinc, Cadmium, and Mercury

W. Guertler[1] found beryllium oxide is but sparingly soluble in fused boric oxide. G. Krüss and H. Moraht found that freshly precipitated beryllium hydroxide does not act on boric acid, and barium borate gives no beryllium borate on treatment with beryllium sulphate, but simply the hydroxide. The borate may, however, be obtained by precipitating beryllium chloride soln. with borax soln. or by neutralizing the same with sodium carbonate in presence of a large excess of boric acid. It is a white precipitate, resembling beryllium hydroxide, and has the composition of a basic salt, namely, *pentaberyllium diborate*, $5BeO.B_2O_3$, which B. Bleyer and L. Paczusky believe is a solid soln. of boric acid in beryllium hydroxide. They found that the ratio of distribution of boric acid between water and beryllium hydroxide is independent of the conc. of the boric acid at 20° and at 100°, showing that no definite compounds can be formed by the action of aq. soln. of boric acid and beryllium hydroxide, and that the boric acid removed by the hydroxide forms a solid soln. The conc. of the solid soln. formed when aq. soln. of beryllium sulphate and borax are mixed, varies considerably with the conc., and with the relative proportions of the reacting substances. Precipitates containing the largest proportions of boric acid are obtained when the beryllium salt reacts with an eq. quantity of sodium borate in a soln. of the highest possible conc. The addition of sodium or ammonium sulphate to the soln. has no appreciable influence on the composition of the precipitate.

The greyish-white mineral *hambergite* is possibly a solid soln., although it is usually regarded as a basic borate in which two of the three hydrogen atoms of boric acid are displaced by beryllium, and the other, by the monad radicle Be(OH), forming **beryllium hydroxyorthoborate,** BeOH.$BeBO_3$. It was first found by W. C. Brögger near Hegerœn, in Norway; A. Lacroix found it near Imalo, in Madagascar; R. C. Burton found crystals at Cashmir in India; and H. Bäckström at Jacobsberg. According to W. C. Brögger, the crystals are rhombic with axial ratios $a : b : c = 0.79876 : 1 : 0.72669$; and they have also been studied by V. Goldschmidt and co-workers, by A. Lacroix, W. J. Sokoloff, and R. C. Burton. Hambergite is soluble in hydrofluoric acid. H. Haga and F. M. Jäger obtained X-radiograms corresponding approximately with the rhombic holohedral symmetry. The sp. gr. is 2·347; the hardness 7·5; the crystals do not melt in the blowpipe; the double refraction is strongly positive, and the indices of refraction are:

	Li-line	Na-line	Tl-line
α	1·5542	1·5595	1·5693
β	1·5891	1·5908	1·5928
γ	1·6294	1·6311	1·6331

M. Puaux assumed that magnesium polyborates are formed in order to account for the augmented solubility of boric acid in water containing a little magnesia. C. Tissier found hydrated magnesium carbonate is soluble in a boiling soln. of boric acid, but the anhydrous salt is insoluble, and calcined magnesia dissolves slowly; O. Popp said magnesite is decomposed by a soln. of boric acid in brisk ebullition; and magnesia alba forms a sparingly soluble basic salt. J. C. G. de Marignac evaporated to dryness a soln. of boric acid and aq. ammonia mixed with enough ammonium magnesium chloride to give the ratio $H_3BO_3 : MgO = 1 : 2$ by weight. After these mixtures had been heated to redness, and washed with water, the boric acid is fixed as magnesium borate, mixed with the excess of magnesia. G. C. Wittstein found cold aq. soln. of magnesium salts are not precipitated by soln. of borax, and, as shown by F. Wöhler, the precipitate formed when the soln. is heated redissolves on cooling. Similar results obtain with a cold sat. soln. of borax and an aq. soln. of potassium carbonate and magnesium chloride. O. Popp said that the borates of ammonia, the alkalies, and of calcium form magnesium borate when heated with a magnesium salt.

J. J. Ebelmen melted magnesium oxide with an excess of boric oxide, and found that the glassy mass loses boric oxide in the pottery oven, and forms on cooling a radiating mass of crystals of **magnesium orthoborate,** $3MgO.B_2O_3$, or $Mg_3(BO_3)_2$. W. Guertler obtained similar crystals. H. le Chatelier melted a mol of boric oxide with 2·5 mols of magnesia, and floated off the crystals with methylene iodide. L. Ouvrard melted at a red heat equi-molar proportions of boric oxide and potassium fluoride along with a slight excess of magnesium oxide. The cold powdered mass was extracted with boiling water and dil. acetic acid. K. A. Hofmann and K. Höschele made crystals of the orthoborate by fusing magnesium chloride with boric oxide. The fine needle-like crystals of magnesium orthoborate, according to E. Mallard, belong to the rhombic system, and have axial ratios $a : b : c = 0.6412 : 1 : 0.5494$. J. J. Ebelmen gave 2·987 for the sp. gr. L. Ouvrard said that boiling water does not attack the crystals, that dil. acetic acid attacks them slowly, and that dil. mineral acids attack them easily. According to F. Wöhler, **enneahydrated magnesium orthoborate,** $Mg_3(BO_3)_2.9H_2O$, is produced by precipitation from a boiling soln. of magnesium sulphate with a soln. of borax, and washing the precipitate with cold water. He also obtained a similar precipitate by boiling a soln. of sodium magnesium borate, and C. F. Rammelsberg added that the boiling must be continued for a long time, and the liquid filtered hot; the precipitate has to be washed with cold water because hot water would withdraw a portion of the acid; it is then dried over sulphuric acid. The fresh precipitate is gelatinous, the dried precipitate is white and gritty. It is slightly soluble in cold water; the soln. has an alkaline reaction, becomes turbid when boiled, and on evaporation leaves a transparent varnish. By a protracted boiling with water, boric acid is withdrawn from the salt.

G. Tammann found the heat of soln. of **magnesium metaborate,** $Mg(BO_2)_2$, glass in *N*-HCl to be 719 cals. per gram, and of the crystals, 59 cals. per gram. Hence the heat of crystallization is 120 cals. per gram. The sp. ht. of both crystals and glass was 0·247.

The mineral *szaibelyite* or *boromagnesite* was found by K. F. Peters in needle-like crystals and grains in the limestone at Werksthal (Hungary) and at Vasko (Krassoszoreny). The analyses of A. Stromeyer, and F. Sommaruga agree with the formula $3(5MgO.2B_2O_3).8(\text{or } 4)H_2O$; it is usually represented by the formula $Mg_5B_4O_{11}.1\frac{1}{2}H_2O$. The sp. gr of the needles is 2·7, and that of the grains, 3·0; the hardness is 3–4. Szajbelyite melts to a white slag in the blowpipe flame; it is optically negative; and the index of refraction $\omega=1·65$, and $\epsilon=1·59$. F. Slavik gave 1·575–1·600 for the refractive index. It is insoluble in hydrochloric acid. The mineral *paternoite* was found in the salt-deposits at Mount Sambuco, Calasibetta, Sicily. Its composition corresponds with $MgO.4B_2O_3.4H_2O$, or $H_8MgB_8O_{17}$, and it contains admixed carnallite and blœdite. It is white and granular, and is made up of minute rhombic laminæ; it is slightly deliquescent; mean refractive index 1·475; it is partially soluble in water with an alkaline reaction; and is readily soluble in dil. acids.

According to W. Guertler, when magnesia is heated with an excess of boric oxide, the fused magma separates into two layers, and on cooling, the lower layer forms a mass resembling marble. It is not homogeneous because different parts have a different sp. gr. If it be treated with water, small crystals of **dimagnesium diborate,** $2MgO.B_2O_3$, or $Mg_2B_2O_5$, are formed, and the excess of boric oxide is washed away. The crystals are doubly refracting; they do not dissolve in water, but do so in a dil. soln. of sodium carbonate. The monohydrate, $2MgO.B_2O_3.H_2O$, occurs in nature as the mineral *ascharite* discovered by W. Feit in nodules of rock salt and kainite from Schmidtmannshall. C. Ochsenius did not find ascharite, but, according to J. H. van't Hoff, H. Precht obtained it at Neu-Stassfurt along with kainite and leonite. W. Feit supposed that its formula was $3Mg_2B_2O_5.2H_2O$, but J. H. van't Hoff showed that it contained rather more water. P. Groth represented it as the normal salt of diboric acid: $Mg=O_2=B-O-B=O_2=Mg$, but J. H. van't Hoff regarded it as *magnesium hydroxyorthoborate*, $Mg=O_2=B-OH$. J. H. van't Hoff obtained it from a soln. of boracite at 83°, or by heating to 150° pinnoite with an aq. soln. of sodium chloride for 8 days. The needle-like crystals are sparingly soluble in $\frac{1}{10}N$-hydrochloric acid. W. Feit first gave 1·85 for the sp. gr. of ascharite, but afterwards changed it to 2·45. H. E. Boeke gave 2·65, dried at 90°, and J. H. van't Hoff gave 2·70. H. E. Boeke gave 1·54 for the mean refractive index of the doubly refracting crystals of ascharite. The rhombic mineral *camsellite* from Douglas Lake, British Columbia, has the same composition, $2MgO.B_2O_3.H_2O$, when allowance is made for the impurities. H. V. Ellsworth and E. Poitevin gave for the refractive indices $\alpha=1·575$, and $\gamma=1·649$. About 2·95 per cent. of the water is lost at 550°.

W. Heintz claimed to have made salts corresponding with $5MgO.4B_2O_3$ and with $7MgO.4B_2O_3$, by careful levigation from the products obtained in their process for the preparation of boracite—*vide infra*. A. Ditte claimed to have made flat needles of *trimagnesium tetraborate*, $3MgO.2B_2O_3$, by melting a mol of magnesia with 2 mols of boric oxide, heating the product with a mixture of sodium and potassium chloride, and washing out the salt. It is soluble in sulphuric or nitric acid. A. Ditte also made needle-like crystals of *magnesium diborate*, $MgO.B_2O_3$, by heating the preceding borate with sodium and potassium chlorides; but neither H. le Chatelier nor W. Guertler could prepare this salt, or the preceding one.

The mineral *pinnoite*, **trihydrated magnesium diborate,** $Mg(BO_2)_2.3H_2O$, as yellowish coloured crystals, was found by H. Staute in the upper layers of the kainite zone of the Stassfurt salt deposits. L. Löwe and E. Erdmann supposed it to be a transformation product of boracite. Analyses by H. Staute, and J. H. van't Hoff and G. Bruni agree with the formula just indicated. The latter prepared it by mixing 100 grms. of borax dissolved in 450 grms. of water, with 53 grms. of hexahydrated magnesium chloride in 50 grms. of water, and warming on a water-bath.

A further 70 grms. of the last-named salt in 60 grms. of water were added and the soln. conc. by evaporation. It was then seeded with pinnoite, and left in a closed vessel on a water-bath at 100°. After 5 days bunches of needle-like tetragonal bipyramids were formed, with axial ratios $a : c := 1 : 0{\cdot}7609$. The crystals were studied by O. Lüdecke and H. E. Boeke. H. Staute gave 2·27 for the sp. gr.; O. Lüdecke, 2·37; and H. E. Boeke, 2·292. The hardness is 3–4. H. E. Boeke gave $\omega = 1{\cdot}565$ and $\epsilon = 1{\cdot}575$ for the indices of refraction. The salt readily dissolves in warm mineral acids; when boiled with water, an alkaline liquid and a flocculent precipitate are formed. The latter redissolves as the soln. cools. When the filtrate is evaporated some boric acid appears. J. H. van't Hoff has studied the paragenesis of pinnoite with löweite, langbeinite, tachhydrite, and sylvite.

J. J. Ebelmen fused together magnesia and boric acid and obtained in addition to the orthoborate, prismatic crystals of **magnesium tetraborate**, $Mg_3B_4O_9$, which E. Mallard found to belong to the triclinic system, and to have the axial ratios and angles $a : b : c = 1{\cdot}795 : 1 :$ $\alpha = 91° 47'$, $\beta = 123° 46'$, and $\gamma = 77° 12'$.

A. Ditto prepared what he regarded as *tetrahydrated magnesium diborate*, $Mg(BO_2)_2.4H_2O$, by heating to over 70° a mixture of magnesia alba and a soln. of boric acid sat. at 30°–40°; the hot filtrate was then heated to a rather higher temp. The precipitate redissolves on cooling the soln., but if most of the hot mother liquor be decanted, the precipitate forms colourless prismatic crystals on standing a few hours at 3°. F. Wöhler prepared **octohydrated magnesium diborate,** $Mg(BO_2)_2.8H_2O$, by heating an aq. soln. of magnesium sulphate and borax till it becomes turbid. The precipitate redissolves on cooling, and if kept for some months below 0°, tufts of long, slender, transparent needles are formed. H. Rose said that if equi-molar parts are used, the precipitate does not have a constant composition. A. Laurent made the octohydrate by the action of magnesium nitrate on a boiling soln. of borax; and J. H. van't Hoff from a warm soln. of 53 grms. of hexahydrated magnesium chloride and 100 grms. of borax in water. O. Popp also made the same salt by the action of a boiling soln. of boric acid sat. with magnesia. According to F. Wöhler, the crystals become milk-white and lose their water of crystallization when heated; they are not soluble in cold or hot water, but they are readily soluble in hydrochloric acid. Boric acid crystallizes from the soln. in warm hydrochloric acid, and ammonia precipitates the salt in fine needles.

A. Ditto reported the formation of *trimagnesium octoborate*, $3MgO.4B_2O_3$, by heating magnesia with a large excess of boric oxide to a white-heat in a carbon crucible. The needle-like crystals are soluble in hot dil. mineral acids, but not in acetic acid. Neither H. le Chatelier nor W. Guertler could confirm A. Ditte's result. A. Ditto also claimed to have made crystals of the hexahydrate, $3MgO.4B_2O_3.6H_2O$, by keeping for 4 or 5 weeks mixed cold conc. soln. of borax and magnesium nitrate. H. le Chatelier claimed to have made *dimagnesium hexaborate*, $2MgO.3B_2O_3$, by melting a mol of boric oxide with 2·5 mols of magnesia. The excess of boric oxide was removed by boiling water. If an excess of magnesia is used the orthoborate is formed and it can be separated by methylene iodide. W. Guertler could not confirm the existence of H. le Chatelier's product.

F. Wöhler claimed to have made *octohydrated magnesium hexaborate*, $MgO.3B_2O_3.8H_2O$, but J. H. van't Hoff and G. Bruni showed that the salt is probably **heptahydrated magnesium hexaborate,** $MgB_6O_{10}.H_2O$. F. Wöhler boiled an excess of a soln. of boric acid with magnesium hydroxide or magnesia alba, and evaporated the filtered soln. to the point of crystallization; J. H. van't Hoff and G. Bruni saturated a hot soln. of one part of boric acid in ten parts of water with magnesia or magnesium carbonate, and slowly conc. the filtered soln. by evaporating at 60° to 70°. F. Wöhler said that when the salt is heated, it loses water and boric oxide, and leaves a fused spongy mass. C. F. Rammelsberg found 100 parts of water dissolve 1·33 parts of the salt. F. Wöhler found that the aq. soln. has an alkaline reaction, and gives up boric acid to boiling water, leaving a residue of magnesium hydroxide. The aq. soln. does not become turbid when boiled, and only conc. soln. give a precipitate with aq. ammonia.

A. Laurent boiled magnesium carbonate with an excess of a soln. of boric acid, and after separating the crystals of boric acid from the filtered soln., obtained crystals of what he regarded as *trihydrated magnesium octoborate*, $MgO.4B_2O_3.3H_2O$; and A. Ditte obtained small crystals of the salt by heating an excess of magnesia alba to 70° with a soln. of boric acid sat. at 30°–40°, and evaporating the filtered soln. A. Laurent obtained no precipitate by adding potassium dodecaborate to a soln. of a magnesium salt, but C. F. Rammelsberg claimed to have obtained *octodecahydrated magnesium dodecaborate*, $MgO.6B_2O_3.18H_2O$, during the preparation of the hexaborate by F. Wöhler's process.

L. B. Guyton de Morveau[2] obtained an opaque glass by fusing one part of magnesia with three parts of borax; and J. J. Berzelius stated that magnesia behaves like calcium oxide towards fused borax. According to L. Gmelin, the spontaneous evaporation of a mixed soln. of borax with an excess of magnesium sulphate furnishes crystals containing boric acid and magnesium and sodium sulphates which he first regarded as forming a quadruple salt, but later showed to be a mixture. F. Wöhler found that the evaporation of a soln. of magnesia in one of borax furnishes small crystals of what he thought to be sodium magnesium borate; and he obtained **sodium magnesium decaborate,** $Na_2O.2MgO.5B_2O_3.30H_2O$, by allowing a cold aq. soln. of magnesium sulphate and borax to stand for some months—fine needles of octohydrated magnesium diborate first appear, and afterwards large crystals of the double salt. C. F. Rammelsberg found that with two mols of borax to one or two mols of magnesium sulphate borax first crystallizes, and then the double salt. The crystals belong to the monoclinic system, and, according to C. F. Rammelsberg, have the axial ratios $a:b:c=1·1761:1:11206$, and $\beta=112°\ 26'$, and effloresce slightly in air. They swell up and lose water when heated. The ignited mass redissolves slowly in cold water excepting a small residue of magnesium orthoborate. If a crystal be placed in hot water, it becomes opaque, and if reduced to powder, the interior consists of a viscid mass. The salt is about as soluble in water as borax, and the soln. is not precipitated by ammonia. When the aq. soln. is heated, it becomes turbid, depositing magnesium orthoborate, which redissolves as the soln. cools. The salt is readily decomposed by water.

C. F. Rammelsberg found that an aq. soln. of a mol of potassium borate and two mols of magnesium chloride furnishes crystals of potassium chloride, and a syrupy mother liquid which solidifies to a crystalline mass. The mineral *kaliborite* was reported by W. Feit in the Stassfurt salts, along with pinnoite and kainite; according to J. H. van't Hoff, it has the composition **enneahydrated potassium magnesium henadecaborate,** $KMg_2B_{11}O_{19}.9H_2O$, or $K_2O.4MgO.11B_2O_3.18H_2O$; analyses were also made by W. Feit, L. Milch, and O. Lüdecke. J. H. van't Hoff suggested that the mineral was formed from pinnoite in contact with a sat. soln. of kainite, and he has worked out the conditions under which it is formed, as well as several methods of preparation. The simplest method is founded on the observation that kaliborite in water at 100° is only slowly converted into pinnoite, and that the presence of boric acid almost entirely prevents the change. The acid borate of magnesium, $MgO.3B_2O_3.7H_2O$, was prepared by adding magnesium hydroxide to 30 grms. of boric acid dissolved in water, and the soln. was conc. to 75 c.c. To this was added another soln. containing 3·6 grms. of potassium hydroxide and 10 grms. of boric acid in 30 c.c. of water. If the mixture was kept at 100° and stirred to prevent the formation of crust, about 13 grms. of kaliborite were obtained. L. Milch found the crystals to belong to the monoclinic system, and to have axial ratios $a:b:c=1·2937:1:1·7539$, and $\beta=99°\ 48'$. The double refraction is positive. W. Feit found that the mineral has a sp. gr. 2·05 at 20°; O. Lüdecke, 2·109–2·129 at 10°; and L. Milch, 2·127; J. H. van't Hoff found the artificial crystals have a sp. gr. 2·081 at 25°. The mineral was found by W. Feit to fuse with difficulty; to be sparingly soluble in water, forming an alkaline soln.; and to be very soluble in mineral acids. J. H. van't Hoff and L. Lichtenstein prepared rhombic crystals of a compound, $2K_2O.2MgO.11B_2O_3.20H_2O$, analogous to kaliborite by the action of a sat. soln. of potassium chloride and boric acid on pinnoite at 40°. The double borate *heintzite*, $K_2Mg_4B_{22}O_{38}.14H_2O$, is also said to occur in the Stassfurt deposits.

The mineral *hydroboracite*, **hexahydrated calcium magnesium hexaborate,** $CaMgB_6O_{11}.6H_2O$, was found by G. Hess in some Caucasian minerals. It occurs in foliated and fibrous masses resembling gypsum, but is rather more fusible. It is slightly soluble in water, forming a soln. with an alkaline reaction. It is also soluble in nitric and hydrochloric acids.

According to W. Guertler,[3] zinc oxide dissolves in molten boric oxide, forming two layers; the upper layer, mainly boric oxide, readily dissolves in water with the formation of a little flocculent zinc oxide, while the lower layer is glassy, even if very slowly cooled. Its composition corresponds with **zinc di- or metaborate,** $Zn(BO_2)_2$. Crystals are obtained when the proportion of zinc oxide is raised to that corresponding with **zinc tetraborate,** $3ZnO.2B_2O_3$, or *zinc sesquiborate*, a compound described by H. le Chatelier and J. J. Ebelmen. The crystals, according to E. Mallard, are isomorphous with those of magnesium and manganese; and they belong to the triclinic system. By melting equi-molar proportions of boric oxide, zinc oxide, and potassium hydrofluoride, L. Ouvrard obtained prismatic crystals of **zinc orthoborate,** $3ZnO.B_2O_3$, or $Zn_3(BO_3)_2$. This compound is decomposed by water and is readily dissolved by dil. acids.

F. Borchers found that boric acid does not react with zinc oxide or hydroxide to form zinc borate, although some zinc does pass into soln. Boric acid and zinc carbonate react readily. Borax does not give a precipitate when added to a soln. of sodium zinc oxide. J. Tünnermann, and T. C. N. Broeksmit obtained a white insoluble zinc borate by mixing aq. soln. of borax and zinc sulphate. The product is used in pharmacy (S. Kraus), and in making a cement for glass (R. Luther and W. Ostwald). H. Rose said that the precipitate obtained in the cold, and washed with cold water, contained principally $9ZnO.4B_2O_3.9H_2O$. E. Holdermann added, with constant stirring, a soln. of 443·6 grms. of borax in 309 grms. of 15 per cent. sodium hydroxide to a soln. of 500 grms. of heptahydrated zinc sulphate in 5–10 litres of water. The precipitate was washed by suction, and dried. Its composition corresponded with $3ZnO.4B_2O_3.H_2O$, or **monohydrated zinc octoborate,** $Zn_3B_8O_{15}.H_2O$. A. Ditte prepared crystals of **decahydrated zinc octoborate,** $ZnO.4B_2O_3.10H_2O$, or $ZnB_8O_{13}.10H_2O$, by digesting at 30° zinc carbonate with a sat. soln. of boric acid, and slowly cooling. A. Rosenheim and F. Leyser could not make complex salts of **zinc pentaborate,** although a soluble salt was formed. A. Ditte also prepared prismatic crystals of **tetrahydrated zinc tetraborate,** $ZnO.2B_2O_3.4H_2O$, or $ZnB_4O_7.4H_2O$, by heating a soln. of the preceding salt to about 50°, and leaving the precipitate for some time in contact with the greater part of the mother liquid when it gradually crystallizes; and by boiling zinc hydrocarbonate with a sat. soln. of boric acid—the precipitate gradually crystallizes in the course of a few days. The product is soluble in water with decomposition and liberation of boric acid; if repeatedly washed with water, zinc oxide remains as a residue.

F. Borchers found that the precipitate obtained by adding borax to a soln. of a zinc salt is very variable, owing to hydrolytic changes. The equilibrium condition is assumed to be $[B_2O_7''][H_2O']^3[Zn^{\cdot\cdot}]=K[H_3BO_3]^2[Zn(BO_2)_2]$. The largest yield is obtained by adding a conc. soln. of a zinc salt to a slight excess of a sat. soln. of borax. Supersaturated soln. or solid borax give higher results. An excess of the zinc salt diminishes the yield by forming complex zinc salts; neutral salts also diminish the yield; magnesium chloride, for instance, prevents precipitation completely. If the hydrolysis of the borax is checked by adding boric acid, the whole of the borax and even part of the boric acid may be precipitated by the zinc salt. The precipitation is rendered more complete if a small proportion of sodium hydroxide is present. E. Büscher said that if a soln. of 20 parts of borax and 60 parts of zinc sulphate be mixed at 50°–60°, the white precipitate of basic sulphate is free from borate; but if a soln. of zinc sulphate be poured into an excess of a hot soln. of borax, the white voluminous precipitate of zinc borate is free from sulphates. By dissolving the precipitate in ammonia, and mixing the liquid with a soln. of boric acid in aq. ammonia, and adding alcohol, E. Büscher obtained rhombic prisms of

hexahydrated zinc tetrammino-tetraborate, $4ZnO.2B_2O_3.4NH_3.6H_2O$; the same compound was obtained by evaporating a soln. of 20 parts of basic zinc carbonate in acetic acid, saturating the liquid with ammonia, and adding 38 parts of boric acid dissolved in aq. ammonia. The crystals separate when alcohol is added. The crystals decompose in air, but may be preserved under ammoniacal alcohol. They are soluble in aq. ammonia, and acids.

F. Stromeyer prepared a cadmium borate, with 27·9 per cent. of boric oxide, by mixing soln. of borax and cadmium sulphate. The white powder is sparingly soluble in water. According to H. Rose, the precipitate produced in the cold contains rather more boric oxide than with hot soln., and in the latter case, the pressed, but not washed, precipitate has the composition $3CdO.2B_2O_3.3H_2O$. W. Guertler obtained similar results with cadmium oxide and fused boric oxide, as when zinc oxide was used, and he thus prepared **cadmium di- or meta-borate,** $Cd(BO_2)_2$, or $CdO.B_2O_3$, melting at 875° ±5°. He believed that this salt can be obtained in two different modifications by annealing the glass at 830°–870° or at 670°–690°. L. Ouvrard obtained prismatic crystals of **cadmium orthoborate,** $3CdO.B_2O_3$, or $Cd_3(BO_3)_2$, by the method used for the corresponding zinc salt. A. Rosenheim and F. Leyser made cadmium pentaborate as in the case of the zinc salt.

J. Tünnermann[4] believed that the precipitates he obtained by mixing soln. of mercurous and mercuric salts were respectively *mercurous and mercuric borates*, but A. Gossmann showed that neither compound is formed. A hot soln. of boric acid dissolves no mercurous oxide, does not give a precipitate with soln. of mercurous nitrate, and if evaporated with mercurous nitrate may be extracted from the dry residue with alcohol; borax gives a precipitate of basic nitrate, free from borates when added to a soln. of mercurous nitrate. Products free from borates are also obtained, according to H. Rose, by rubbing together mercurous nitrate and borax, and also, according to E. F. Anthon, by adding a soln. of borax previously neutralized with boric acid to a soln. of mercurous nitrate. Mercuric salts behave similarly, A soln. of ammonium borate acts on mercury salts like aq. ammonia. M. G. Levi and S. Castellani obtained no sign of a mercury borate by the electrolysis of a soln. of boric acid in the cathode cell and a soln. of a mercury salt in the anode cell.

§ 13. The Borates of Aluminium, Thallium, and the Elements of the Rare Earths

The evidence for the existence of definite **aluminium borates** is very unsatisfactory. Alumina was found by W. Guertler[1] not to be particularly soluble in molten boric oxide; and, according to J. J. Ebelmen, alumina mixed with boric oxide is not altered when heated in a pottery oven, but with borax the alumina is changed to corundum. E. Mallard represented J. J. Ebelmen's product by the formula $3Al_2O_3.B_2O_3$, or $(AlO)_3BO_3$, and found the rhombic crystals had the axial ratios $a : b : c = 0·974 : 1 : 0·679$. L. Troost and P. Hautefeuille found that alumina is volatilized when heated in the vapour of boron trichloride. E. Frémy and F. Feil found that an aluminium borate is formed when boric oxide is heated with aluminium fluoride; F. Wöhler and H. St. C. Deville showed that aluminium borate is formed along with the boride when boric oxide is heated with aluminium; the borate is decomposed by water.

C. Tissier showed that alumina does not dissolve in an aq. soln. of boric acid; and A. Ditte found that aluminium hydroxide does not dissolve, but takes up boric acid, forming $Al_2O_3.B_2O_3$ when the product is dried. C. Tissier found a precipitate is produced when a soln. of an aluminium salt is treated with a soln. of boric acid which has been neutralized with borax. According to H. Rose, when borax or sodium metaborate is added to a cold aq. soln. of potash alum, a precipitate containing some absorbed soda is produced; this is removed by washing with water, and the product dried at 100° had composition varying between $2Al_2O_3.B_2O_3.5H_2O$ and $3Al_2O_3.2B_2O_3.8H_2O$. There is nothing here to show that a definite aluminium borate is formed, and F. Jean and E. Reichardt, A. Ditte, and J. Martenson found that the precipitate obtained by adding borax to a soln. of aluminium salt is completely hydrolyzed to aluminium hydroxide when thoroughly washed.

P. W. Jeremejeff[2] obtained from Nertschinsk, Siberia, masses of crystals of a basic aluminium borate to which A. Damour ascribed the formula $(Al_2O_3.Fe_2O_3)B_2O_3$, based on the analysis: B_2O_3, 40·19; Al_2O_3, 55·03; Fe_2O_3, 4·08; K_2O, 0·70. P. Groth ascribed to it the generalized formula $AlO.BO_2$. The outer portions of these masses are hexagonal crystals, called *jeremejeffite*, with axial ratio $a : c = 1 : 0·68351$, and the interior consists of rhombic crystals, called *eichwaldite*, with axial ratios $a : b : c = 0·5523 : 1 : 0·5434$. The sp. gr. is 3·28, the hardness 6·5; and the index of refraction 1·64. The optical properties of jeremejeffite are anomalous, and were examined by P. W. Jeremejeff, C. Klein, and R. Brauns.

The mineral *rhodizite*—from ῥοδίζειν, in allusion to its colouring a flame red—is likewise a basic aluminium potassium borate. It was obtained by G. Rose[3] in minute white crystals on red tourmalines from Sarapulsk, and Schaitansk near Keitharinenburg; A. Lacroix found crystals at Bity, Antandrokomby, and Munjaka, in Madagascar; and L. Duparc, at Ampakita in Madagascar. The first of the following analyses, by A. Damour, refers to a sample from the Urals; the second, by F. Pisani, to a sample from Antandrokomby; and the third, by A. Lacroix, to a sample from Bity:

B_2O_3	Al_2O_3	BeO	K_2O	Na_2O	Li_2O	SiO_2	Loss on ignition.	Water.
33·93	41·40	—	12·00	1·62	—	—	2·98	95·40
40·60	30·50	10·10	5·90	3·30	7·30	1·36	0·45	99·51
41·69	30·70	10·36	6·05	3·38	7·36	—	0·46	100·00

The first one also had 0·74, CaO; 0·82, MgO; 1·93, FeO. A. Damour represented his results by $R_2O.2Al_2O_3.3B_2O_3$; F. Pisani, by $4(Li, K, Na, H)_2O.4BeO.3Al_2O_3.6B_2O_3$; and P. Groth gives the generalized formula, **potassium aluminoborate,** $(AlO)_2K(BO_2)_8$. The crystals belong to the cubic system. The sp. gr. is 3·415; the hardness is 8, for the mineral scratches topaz. The index of refraction, according to L. Duparc, is 1·6895 for the Li-light, 1·6935 for the Na-light, and 1·6965 for the Tl-light. E. Bertrand, C. Klein, R. Brauns, and J. Beckenkamp have studied the anomalous double refraction. The crystals fuse to an opaque glass when heated in the blowpipe flame; they dissolve in fused borax, or microcosmic salt; and they dissolve with difficulty in hydrochloric acid.

C. H. Burgess and A. Holt,[4] and W. Guertler found thallium oxide or carbonate dissolved in fused boric acid, forming a clear glass, or a crystalline solid. M. Hebberling obtained no precipitate on adding a soln. of borax to a conc. soln. of thallous salts; but W. Crookes found that boric acid and thallous carbonate, or borax and thallous sulphate, give a white granular precipitate insoluble in cold dil. sulphuric acid, and soluble in boiling water. H. Buchtala prepared **thallous tetraborate,** $Tl_2B_4O_7.2H_2O$, by crystallization from an aq. soln. of a mol of thallous carbonate and 1 to 4 mols of boric acid; it is also formed by fusing a mol of thallous carbonate with 6 mols of boric acid, extracting the cold mass with water, and allowing the soln. to crystallize. The tetraborate is here accompanied by more **thallous hexaborate,** $Tl_2B_6O_{10}.3H_2O$. If more boric acid is used, say 8 mols, a mixture of the hexaborate and **thallous decaborate,** $Tl_2B_{10}O_{16}.8H_2O$, is formed. **Thallous octoborate,** $Tl_2B_8O_{13}.4H_2O$, and **thallous dodecaborate,** $Tl_2B_{12}O_{19}.7H_2O$, are formed when a mol of thallous carbonate is dissolved in an excess, say 10 mols, of an aq. soln. of boric acid. The dodecaborate also forms twinned monoclinic crystals of a pentahydrate with axial ratios, according to R. Scharizer, $a : b : c = 1·583 : 1 : 1·955$, and $\beta = 94° 25'$. A. Rosenheim and F. Leyser made **thallous pentaborate. Thallous metaborate** is formed by evaporation from an aq. soln. of the perborate. The colourless wedge-shaped crystals have the composition $TlBO_2.\frac{1}{2}H_2O$; they become dark red on exposure to air. G. Canneri and R. Morelli found that the fusion curve, Fig. 29, of mixtures of thallous oxide and boric oxide has three maxima corresponding with thallous metaborate, $TlBO_2$, m.p. 472°; thallous pyroborate, $Tl_4B_2O_5$, of m.p. 434°; and normal thallous borate, Tl_3BO_3, of m.p. 370° with decomposition.

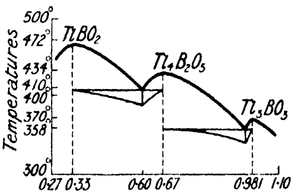

FIG. 29.—Fusion Curves of Mixtures of Thallous and Boric Oxides.

The metaborates of the rare earths have been discussed by W. Guertler,[5] A. E. Nordenskjöld, O. Holm, etc. According to N. J. Berlin, boric acid gives with neutral and acid salts of ytterbium a white precipitate of **ytterbium borate,** which readily attracts carbon dioxide from the atm. J. J. Berzelius found that boric acid precipitates white flocculent thorium borate when added to a soln. of a salt of that element; the precipitate is insoluble in an excess of boric acid. G. Karl treated an aq. soln. of thorium nitrate with a hot soln. of borax until a permanent precipitate was formed; this was washed and dried at 400°–500°. The composition of the amorphous white mass corresponded with **thorium orthoborate,** $Th_3(BO_3)_4$. It is decomposed by water. W. Guertler could not make a thorium borate by fusing thoria with boric oxide on account of the very sparing solubility of the thoria. A. E. Nordenskjöld reported the formation of a basic **lanthanum borate,** $2La_2O_3.B_2O_3$, by fusing borax with lanthanum oxide in a pottery oven; but experiments to prepare *didymium borate* in a similar way were not satisfactory. W. Guertler obtained **lanthanum metaborate,** $La(BO_2)_3$, by crystallization from slowly cooled soln. of lanthanum oxalate in boric oxide. The upper layer is mainly boric oxide. W. Guertler found that when boric oxide is fused with cerium oxalate, in a stream of carbon dioxide, two layers are formed; the upper greyish-brown layer is a soln. of cerium oxide in boric oxide, and the lower dark brown layer, when allowed to devitrify, furnishes **cerium metaborate,** $Ce_2O_3.3B_2O_3$, or $Ce(BO_2)_3$; **neodymium metaborate,** $Nd(BO_2)_3$; **praseodymium metaborate,** $Pr(BO_2)_3$; and **gadolinium metaborate,** $Gd(BO_2)_3$, are produced in a similar way. P. T. Cleve said that samarium dissolves in molten borax, forming a topaz-like glass from which, when saturated, microscopic micaceous scales separate. When the powdered glass is treated with dil. hydrochloric acid, **samarium metaborate,** $Sm(BO_2)_3$, remains. The borate is soluble in hydrochloric acid, particularly when heated, so that the isolation of the crystals requires care. The sp. gr. is 6·048 at 16·4°. W. Guertler found erbia and yttria to be insoluble or only very sparingly soluble in boric oxide. According to W. Crookes, scandium hydroxide suffers virtually no change when triturated with a soln. of boric acid, but a slight combination occurs when the mixture is boiled. A mixture of boric oxide and scandia forms a clear liquid when fused at a bright red heat; and after lixiviation of the cold mass, a white microcrystalline powder remains. Analyses correspond with **scandium orthoborate,** $ScBO_3$.

§ 14. The Borates of Tin, Lead, and Zirconium

C. F. Wenzel[1] found that a soln. of stannous chloride gives a white precipitate when treated with borax. According to M. Kaatz, the precipitate is a mixture of stannous hydroxide and boric acid, and it is not obtained in soln. feebly acidified with hydrochloric acid; and the boric acid is removed from the assumed stannous borate by washing twice with water. A. C. Campbell boiled stannous chloride with hydrochloric acid and tin to ensure that all was converted into stannous salt; he then added sodium carbonate until a permanent precipitate commenced to form; the mixture was then treated with enough borax to convert all the tin into *stannous borate*. The precipitate was found to remain unaltered after 12 hrs.' exposure to air, and he therefore recommended it to be used in the preparation of standard soln. of stannous salts. W. Guertler found that in his attempts to make stannous borate, the product decomposed into tin, stannic oxide, and boric oxide. C. H. Burgess and A. Holt, and W. Guertler found stannic oxide to be insoluble in molten boric oxide. The rare mineral *nordenskiöldine* was found in rhombohedral crystals by W. C. Brögger in the pegmatite veins of the Island of Gross-Arö south of Christiania, Norway. An amphibole from Ruscula, Lake Onega, was named *nordenskiöldite* by Kenngott. The colour of W. C. Brögger's mineral is yellow, its sp. gr. is 4·20, and its hardness, 5½ to 6. Its analysis corresponds with **calcium stannic borate,** $CaSn(BO_3)_2$, or less probably $Ca(BO)_2SnO_4$. The stannate formula is preferred by P. Groth, but W. C. Brögger said that the crystalline form is against that assumption. The trigonal crystals were found by W. C. Brögger to have the axial ratio $a:c=1:0·8221$, and $\alpha=102° 58'$. L. Ouvrard synthesized the mineral by heating a mixture of calcium tetraborate and stannic oxide in a stream of hydrochloric acid; or by passing the vapour of stannic chloride over the red-hot borate. The colour of the mineral is yellow. L. Ouvrard's preparation forms colourless transparent hexagonal plates. The sp. gr. of the mineral is 4·20, that of L. Ouvrard's preparation is 4·8 at 15°. The hardness of the mineral is 5·5–6·0. L. Ouvrard made the corresponding **strontium stannic borate,** and **barium stannic borate.**

M. Faraday[2] found that a fused mixture of 112 parts of lead oxide and 24 of boric acid forms a soft yellow glass of sp. gr. 6·4, which softens on immersion in boiling oil, and is blackened by hydrogen sulphide; if 72 parts of boric acid are used, the glass is colourless, as hard as flint glass, and possesses a high refracting power. According to W. Guertler, mixtures of boric oxide and lead oxide melt, forming clear glasses, which, on cooling, may furnish emulsions. The phenomenon is analogous with that observed with mixtures of say phenol and water (**1.** 10, 3—Fig. 11); and the temp. at which an emulsion of lead and boric oxides is produced is shown in Fig. 30. Mixtures containing between 0·0008 and 0·0725 eq. of $(PbO)_3$ per eq. of B_2O_3 alone show this turbidity during cooling, and the two legs *ac* and *bc* are solubility curves respectively of lead oxide in boric oxide and of boric oxide in lead oxide. At temp. exceeding *c*, clear glasses are produced and the two oxides are mutually soluble in all proportions. Mixtures with more than $0·0725(PbO)_3.B_2O_3$ furnish clear glasses on cooling. The glasses are either colourless or tinged faintly yellow;

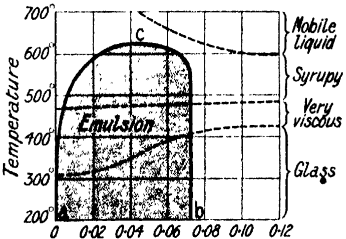

Fig. 30.—Solubility Curve of Lead Oxide in Boric Oxide.

they are insoluble in water; and are decomposed by hydrogen sulphide. There is here no sign of the formation of definite lead borates. A few lead borates have been reported as precipitates formed by double decomposition, but so long as chemical analyses alone are available there will be doubts as to the chemical individuality of the observed products.

According to J. Tünnermann, if an excess of borax be added to lead nitrate, at ordinary temp. or boiling, a white precipitate is obtained containing $PbO.1{\cdot}3B_2O_3$; while if the borax soln. be mixed with enough boric acid to give it an acid reaction, a white precipitate is formed containing $PbO.2{\cdot}6B_2O_3$. G. Rose reported that hydrated **lead metaborate,** $Pb(BO_2)_2.H_2O$, is formed as a white precipitate when a soln. of borax and a neutral soln. of lead nitrate are mixed in the presence of aq. ammonia. H. V. Thompson obtained the same compound. The white powder is insoluble in water and in alcohol, but soluble in nitric or acetic acid without decomposition. The salt is decomposed by sulphuric or hydrochloric acid; and by the alkalies. Lead metaborate melts to a colourless transparent glass. Water is given off at about 120°, but the anhydrous salt is obtained at about 250°. S. Motylewsky found the drop-weight of fused lead metaborate to be 185 mgrms. when that of water at 0° is 100; and the drop-weight of the molten borate to be 185 mgrms. when water at 0°=100. H. Becquerel gave for the index of refraction 1·780; and he found the molten borate exhibited magnetic rotation of the plane of polarized light. J. Rosenthal found the compressed powder did not conduct electricity at 340°, but it does so as the glass softens—*vide* glasses. T. W. B. Welsh and H. J. Broderson found that lead metaborate is soluble in dried hydrazine, and that the soln. conducts electricity badly, forming a black deposit on the cathode.

A number of basic lead borates are produced by mixing soln. of sodium borate and lead nitrate. The basicity depends on the temp., on the conc. of the soln., and on the amount of washing employed. H. Rose thus reported the salts $PbO : B_2O_3 : H_2O = 2 : 1 : 2$; $4 : 3 : 5$; $9 : 3 : 8$; and $6 : 5 : 6$. These represent different stages in the hydrolysis of lead borate, and they are probably mixtures and not compounds. Some polyborates have also been reported. E. Soubeiran obtained **tetrahydrated diplumbic hexaborate,** $2PbO.3B_2O_3.4H_2O$, by precipitation from a boiling soln. of an excess of borax mixed with lead nitrate; the white powder lost half of its combined water between 180° and 200°. H. V. Thompson working with cold soln. obtained only $Pb(BO_2)_2.H_2O$. T. J. Herapath said that the compound fuses to a colourless glass, and he claimed to have prepared **tetrahydrated lead tetraborate,** $PbO.2B_2O_3.4H_2O$, by boiling either of the preceding salts with an excess of soln. of boric acid. He added that 3 mols of water are lost at about 220°. H. V. Thompson could not find any definite compound to be formed by T. J. Herapath's process. H. le Chatelier also claimed to have made anhydrous **lead hexaborate,** $PbO.3B_2O_3$, by fusing together lead carbonate and boric acid, and treating the cold product with water to remove the excess of boric oxide. H. V. Thompson verified this result. According to L. Kahlenberg and W. J. Trautman, lead borate gives a black slag when heated with silicon.

W. Guertler[3] found that silica and zirconia are insoluble or only very sparingly soluble in molten boric oxide; and there is no evidence of the formation of a *silicon borate* or of a *zirconium borate*. F. P. Venable and T. Clark found that zirconia does not dissolve in molten borax. A white precipitate, possibly a *basic zirconium borate*, insoluble in water, is produced when borax is added to a soln. of a zirconium salt. Cerium and thorium borates have been discussed in connection with the rare earth borates.

§ 15. The Borates of the Arsenic and Chromium Families

According to W. Guertler,[1] the oxides of *arsenic*, *antimony*, bismuth, tungsten, vanadium, molybdenum, and uranium dissolve in fused boric oxide more or less sparingly, and on cooling, the oxide may separate from the melted mass, forming an emulsion. H. Rose noted that bismuth oxide readily dissolves in molten borax, forming a glass which with a little bismuth oxide is yellow when hot, and colourless when cold; with more bismuth oxide, orange-red when hot and yellow and opaque when cold. L. Vanino and F. Hartl found that when a borate is added to a soln. of bismuth nitrate and mannite, a white precipitate of **dihydrated bismuth orthoborate,** $BiBO_3.2H_2O$, is formed. According to J. J. Berzelius, bismuth borate is sparingly soluble in water; according to L. Vanino and F. Hartl, it is stable towards potassium hydroxide, and potassium iodide, and is immediately decomposed by hydrogen sulphide.

According to J. J. Berzelius, a soln. of vanadyl sulphate gives with borax a greyish-white precipitate of **vanadyl borate** insoluble in water and soluble in a soln. of boric acid, forming a blue soln. which becomes green on exposure to air, and is decomposed by hydrogen sulphide. A. Guyard melted together vanadic and boric acids, and obtained a pale green glass of **vanadium borate** soluble in water, from which solvent it can be crystallized; but the aq. soln. is unstable, and some hydrolysis occurs.

Molten borax was found by H. Rose, M. Landecker, and L. Weiss to dissolve *columbic oxide*, forming a clear glass which is colourless in both the oxidizing and reducing flame. A. G. Ekeberg, and L. Weiss and M. Landecker found *tantalic oxide* dissolved in fused borax, forming a colourless glass very sparingly soluble in water.

According to A. Moberg,[2] sodium metaborate or tetraborate gives a pale blue *chromous borate* when added to a soln. of chromous chloride. The precipitate is soluble in free acids, but not in an excess of the precipitant. N. J. Berlin obtained a blue precipitate by adding borax to a soln. of a chromic salt, the precipitate is soluble in an excess of the precipitant. M. Hebberling found that borax gives a greyish-green *chromic borate*, $7Cr_2O_3.4B_2O_3$, when added to a soln. of a chromic salt; if the soln. of chromic salt and borax is mixed with ammonia, and the excess of ammonia is expelled by boiling, the precipitate contains less boric oxide, the smaller the excess of borax in the soln. C. Tissier mixed a chromic salt soln. with a large excess of boric acid, and added as much borax to the boiling soln. as was necessary to neutralize the acid of the chromic salt; he found that chromic oxide was precipitated. A. A. Hayes found that ammonium hydrodiborate, $(NH_4)H(BO_2)_2$, gave a pale green precipitate with an aq. soln. of chromic chloride; and A. Laurent found potassium hexaborate gives a green precipitate. A. Rosenheim and F. Leyser made a complex **chromium pentaborate.**

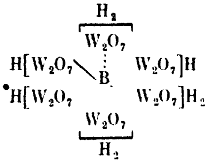
J. J. Berzelius[3] obtained a dark grey precipitate of *molybdous borate* on adding a soln. of borax to a molybdous salt soln. *The precipitate is black when dried; it is insoluble in water, but sparingly soluble in a soln. of boric acid.* A reddish-yellow precipitate of *molybdic borate* is produced when ammonium borate is added to a soln. of molybdic chloride; molybdic hydroxide dissolves in a soln. of boric acid, producing a yellow soln. which, on evaporation, solidifies to a jelly and deposits the normal borate. J. J. Berzelius also showed that a boiling aq. soln. of boric acid dissolves molybdic acid, and when the latter is in excess, produces a viscid liquid. The soln. becomes turbid when cooled, and when the clear filtered liquid is evaporated, colourless crystals are deposited—thought to be *boromolybdic acid.* These crystals are decomposed by alcohol into molybdic and boric acids. C. W. Scheele found that fused borax dissolves tungstic oxide, forming a clear glass, which when overloaded with tungsten becomes brown or white.

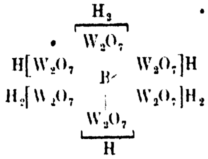
Although boric acid has a marked tendency to form complex salts, it forms well-defined heteropolyacids only with tungstic oxide, the so-called **borotungstates.** J. D. Klein[4] made a borododecatungstic acid, $B_2O_3.12WO_3.nH_2O$, by the method employed by J. C. G. de Marignac for hydrosilicododecatungstic acid. D. Klein also reported borotungstic acids of the composition $B_2O_3.14WO_3.nH_2O$ and $B_2O_3.9WO_3.24H_2O$, which he called respectively *acide borotungstique* and *acide tungstoborique*. H. Copaux considered that both these acids are mixtures of respectively $(6H_2O.B_2O_3.28WO_3)56H_2O$, and $(5H_2O.B_2O_3.24WO_3)61H_2O$. D. Klein made the former by treating the sodium salt with mercurous nitrate, decomposing the product with hydrochloric acid and removing the mercury with hydrogen sulphide; and the latter was made in a similar manner from the sodium salt, or by the action of dil. sulphuric acid on the barium salt. H. Copaux made what he regarded as $6H_2O.B_2O_3.28WO_3.56H_2O$, or $H_6B_2W_{28}O_{93}.56H_2O$, by mixing soln. of sodium tungstate and boric acid in boiling water; decomposing the product with a mineral acid; and extracting the complex acid with ether. The small hexagonal prisms have the axial ratio $a:c=1:0.993$; and on exposure to air they become yellow. A soln. of boiling water soon decomposes the acid with the separation of tungstic acid. A. Rosenheim showed that the analyses agreed with the assumption that the acid is enneabasic **hydroborododecatungstic acid,** $H_9[B(W_2O_7)_6].22H_2O$, and this was confirmed by A. Rosenheim and J. Jänicke.

A. Rosenheim and J. Jänicke prepared the acid $H_9[B(W_2O_7)_6].28H_2O$ by dissolving 100 grms. of sodium tungstate and 150 grms. of boric acid in 400–500 c.c. of boiling water, and boiling the soln. until a sample treated with hydrochloric acid gave no precipitation of tungstic oxide. The cold soln. was separated from the boric acid and sodium borate by suction; mixed with 70 grms. of boric acid; and conc. over the naked flame. The cold soln. was again separated from the crystals by suction, and washed with 33 per cent. sulphuric acid. The liquor was then shaken with 2 to 3 times its vol. of 33 per cent. sulphuric acid and ether. The oily liquor is dissolved in cold water, and the soln. allowed to stand in vacuo over conc. sulphuric acid. A good yield of crystals is thus obtained.

According to A. Rosenheim and J. Jänicke, the *octocosihydrate*, $H_9[B(W_2O_7)_6].28H_2O$, begins to melt at 45°, and at 51° it forms a clear liquid. Soln. of this acid in dil. nitric acid give only the octocosihydrate, and the soln. rapidly decomposes with the separation of tungstic acid; but soln. in conc. nitric acid of sp. gr. 1·4, furnish a white crust of microscopic crystals of a *decahydrate*, $H_9[B(W_2O_7)_6].10H_2O$.

H. Copaux also obtained the acid $5H_2O.B_2O_3.24WO_3.61H_2O$ by treating the soln. used in the preparation of the preceding mother-liquid acid with barium carbonate, and decomposing the barium salt with dil. sulphuric acid. The tetragonal octahedra have the axial ratio $a:c=1:1.010$; and they are isomorphous with silicotungstic acid. They are stable in dry air, but decompose in moist air. H. Copaux said the acid is pentabasic; A. Rosenheim, enneabasic, $H_9[B(W_2O_7)_6].22H_2O$, and the latter hypothesis was confirmed by A. Rosenheim and J. Jänicke. H. Copaux considered these acids to be different hydrates of one acid, but both acids are obtained from the same soln., and the octocosihydrate is not converted into the docosihydrate by heat; A. Rosenheim inferred that it is more likely that the docosi- and the octocosi-hydrates are isomeric forms. The one is called **isohydroborododecatungstic acid,** $H_9[B(W_2O_7)_6].22H_2O$, and other hydroborododecatungstic acid, $H_9[B(W_2O_7)_6].28H_2O$; their composition can be represented by co-ordination formulæ:





For W. and D. Asch's hexite theory of the constitution of the borododecatungstic acids, *vide* silicotungstic acids.

D. Klein prepared an ammonium borotungstate to which he assigned the formula $2(NH_4)_2O.9WO_3.B_2O_3.19H_2O$ by the action of ammonium sulphate on the barium salt; and H. Copaux, one of the composition $5(NH_4)_2O.24H_2O.B_2O_3.52H_2O$ by the action of dil. aq. ammonia on the free acid, and evaporating the soln. in air. The observations of A. Rosenheim and co-workers indicate that the salt is **ammonium isotetrahydroborododecatungstate,** $(NH_4)_5H_4[B(W_2O_7)_6].nH_2O$. The tetragonal crystals have the axial ratio $a:c=1:1·016$; and they are isomorphous with the free acid. The crystals are stable in dry air, but deliquescent in moist air.

H. Copaux made a lithium salt by a process analogous to that employed for the ammonium salt, and from the observations of A. Rosenheim, it is probably **lithium isotetrahydroborododecatungstate,** $Li_5H_4[B(W_2O_7]_6.nH_2O$. It forms triclinic crystals with axial ratios $a:b:c=1·629:1:0·748$, and $\alpha=98° 4'$, $\beta=102° 2'$, and $\gamma=86° 10'$. The crystals are stable in dry air, but deliquescent in moist air. D. Klein reported three sodium borotungstates with $Na_2O:WO_3:B_2O_3:H_2O=2:14:1:29$; $1:9:1:23$; and $2:9:1:12$. K. Ebenhusen also obtained the 2 : 14 : 1 : 29 salt. According to H. Copaux, the 5 : 24 : 1 : 35 salt can be obtained by a similar process to that employed for the ammonium salt, and from A. Rosenheim's observations, it would appear to be **sodium isotetrahydroborododecatungstate,** $Na_5H_4[B(W_2O_7)_6].15·5H_2O$. It forms monoclinic crystals, stable in air, and with the axial ratios $a:b:c=0·461:1:0·569$, and $\beta=97° 17'$. According to A. Rosenheim and H. Schwer, **sodium tetrahydroborododecatungstate,** $Na_5H_4[B(W_2O_7)_6].27H_2O$, is obtained by treating a soln. of the acid with the calculated amount of sodium carbonate, and evaporating the liquid on a water-bath and then over conc. sulphuric acid. The crystals are isomorphous with those of sodium metatungstate. The loss in water at different temp. is:

	110°	120°	140°	160°	300°
Molar loss . . .	27	27	27	28	29

showing that two of the 29 mols of water are constitutional. The eq. conductivity at 25° when an eq. of the acid is contained in v litres of water is:

v	32	64	128	156	512	1024
λ	183·9	196·0	203·2	213·6	225·2	235·2

and $\lambda_{1024}-\lambda_{32}=51·3$ corresponding with a pentabasic salt; but the neutralization curve obtained with progressive additions of $0·1N$-NaOH, to $\frac{1}{64}N$-$Na_5H_4[B(W_2O_7)_6].27H_2O$, and sp. conductivities in reciprocal ohms:

C.c. $\frac{1}{10}N$-NaOH .	0	1	2	2·8	3	4	5	6	7	8
Rec. ohms . .	3·054	2·506	1·96	1·684	1·654	1·89	2·02	2·22	2·48	2·62

has a minimum corresponding with at least two more replaceable atoms of hydrogen. The guanidinium salt, $(CN_3H_6)_6H_3[B(W_2O_7)_6$, is hexabasic; but enneabasic salts have not been obtained with certainty. D. Klein reported potassium salts with $K_2O : WO_3 : B_2O_3 : H_2O = 3 : 14 : 1 : 23$; $2 : 12 : 1 : 18$; $4 : 12 : 1 : 21$; and $2 : 9 : 1 : 13$; and K. Ebenhasen, $5 : 25 : 1 : 34$. H. Copaux reported **potassium trihydroborododecatungstate,** $K_6H_3[B(W_2O_7)_6].21H_2O$, according to A. Rosenheim's formulation. The white hexagonal microscopic prisms were obtained by crystallization from a soln. containing a mol. of the acid and less than 6 mols of potassium carbonate. The salt is completely decomposed by boiling alkali-lye. He also made **potassium isotetrahydroborododecatungstate,** $K_5H_4[B(W_2O_7)_6].18H_2O$, according to A. Rosenheim's interpretation. Hexagonal prisms were obtained by an analogous process to that employed for the ammonium salt. The hexagonal prisms have the axial ratio $a : c = 1 : 0{\cdot}652$; the crystals are optically negative, and have the rotatory power $\alpha_D = 14°$. The crystals lose a mol. of water on exposure to air. D. Klein reported a *silver borotungstate* with $3Ag_2O.14WO_3.B_2O_3.7H_2O$. A. Rosenheim and H. Schwer made **silver isotetrahydroborododecatungstate,** $Ag_5H_4[B(W_2O_7)_6].7H_2O$, as a white crystalline precipitate by adding an aq. soln. of the sodium salt to one of silver nitrate. The existence of the normal salt $Ag_9[B(W_2O_7)_6]$ was not proved.

D. Klein reported a calcium borotungstate, $2CaO.9WO_3.B_2O_3.15H_2O$, and H. Copaux reported **calcium isotetrahydroborododecatungstate,** $Ca_5\{H_4[B(W_2O_7)_6]\}_2.44H_2O$, according to A. Rosenheim's hypothesis. The salt is made by saturating the free acid with an excess of calcium carbonate, and evaporating the liquid. The triclinic crystals have the axial ratios $a : b : c = 1{\cdot}357 : 1 : 1{\cdot}524$, and $\alpha = 82° 20'$, $\beta = 101° 42'$, and $\gamma = 94° 44'$. D. Klein made a *strontium salt*, and a *sodium barium salt*; K. Ebenhusen also reported a barium salt. H. Copaux made tetragonal crystals of **barium isotetrahydroborododecatungstate,** $Ba_5\{H_4[B(W_2O_7)_6]\}_2.54H_2O$, according to A. Rosenheim's interpretation. The axial ratio is $a : c = 1 : 1{\cdot}077$; another salt reported with $6BaO.24WO_3.B_2O_3.58H_{20}$ probably contained admixed barium tungstate.

D. Klein reported *magnesium borotungstate*, and H. Copaux obtained doubly refracting crystals of **magnesium isotetrahydroborododecatungstate,** $Mg_5\{H_4[B(W_2O_7)_6]\}_2.42H_2O$, according to A. Rosenheim's views. The soln. crystallizes badly at ordinary temp. but better at 40°. D. Klein reported a *zinc borotungstate* in rhombic needles, and the sat. aq. soln. has a sp. gr. 3·15; and K. Ebenhusen gave for the ratio $ZnO : WO_3 : B_2O_3 = 2 : 9 : 1$. D. Klein likewise reported *cadmium borotungstate*, $2CdO.9WO_3.B_2O_3.18$(or 19)H_2O, to be formed by treating the barium salt with cadmium sulphate. According to G. Linck, six of the 18 mols of water are combined. The crystals are dimorphous; the rhombic form has the axial ratios $a : b : c = 1{\cdot}3321 : 1 : 1{\cdot}1383$; and the triclinic form, $a : b : c = 0{\cdot}6261 : 1 : 0{\cdot}4398$, and $\alpha = 1{\cdot}14° 56'$, $\beta = 92° 42'$, and $\gamma = 94° 57'$. Eight parts of water dissolve more than 100 parts of the salt at 17°, and the sp. gr. of the sat. soln. at 15·6°/4° is 3·2887; and at 16·2°/4°, 3·2868,—it is the so-called *Klein's solution* used in the separation of minerals. The optical properties of the soln. were studied by G. W. A. Kahlbaum and co-workers. The index of refraction at 20° is 1·5781 for the H_α-line; 1·5836 for the D-line; and 1·5980 for the H_β-line. The dispersion is therefore $\mu_{H_\beta} - \mu_D = 0{\cdot}0144$. The crystals are pleochroic and effloresce readily. At 100° only traces of water are expelled; at 150°, 12 mols are given off; and the remainder at a red heat. H. Copaux made **cadmium isotetrahydroborododecatungstate,** $Cd_5\{H_4[B(W_2O_7)_6\}_2.51H_2O$, according to A. Rosenheim's theory. The triclinic crystals are stable in air. D. Klein reported *mercurous borododecatungstate* to be formed as a yellowish-white precipitate when the potassium salt is treated with mercurous nitrate; he also reported *mercuric borotungstate*. H. Copaux made **mercurous borododecatungstate,** formulated $Hg_9[B(W_2O_7)_6].12{\cdot}5H_2O$, by treating sodium borotungstate with mercurous nitrate; the precipitate is washed with water containing mercurous nitrate, and dried in air. The same salt was made by A. Rosenheim and H. Schwer.

D. Klein reported *aluminium borotungstate*, $2Al_2O_3(9WO_3.B_2O_3)_3.65H_2O$; *didymium borotungstate* in rose-red octahedra; *cerium borotungstate* of indefinite composition; *thallium borotungstate*, $2Tl_2O.9WO_3.B_2O_3.5H_2O$; *chromium borotungstate*,

$2Cr_2O_3(9WO_3.B_2O_3)_3.74H_2O$; *uranium borotungstate*, $3UO_3(9WO_3.B_2O_3)_2.30H_2O$; *manganese borotungstate*, $2MnO.9WO_3.B_2O_3.17H_2O$; *antimonous borotungstate*, and *antimonic borotungstate* by dissolving antimonious or antimonic acid in a boiling soln. of borotungstate acid; and *vanadium borotungstate*, $3V_2O_3(B_2O_3.9WO_3)_2.30H_2O$; D. Klein made *lead borotungstate*, $2PbO.9WO_3.B_2O_3.12H_2O$, in two forms: one, in rhombic crystals, by treating the acid with lead carbonate; and another, by *evaporation spontanée* of a mixed soln. of sodium borotungstate, and lead nitrate. These salts are decomposed by water. He made *ferric borotungstate*, and *ferrous borotungstate* of undetermined composition; and he also obtained *cobalt borotungstate*, $2CoO.9WO_3.B_2O_3.18H_2O$, in monoclinic crystals isomorphous with the nickel salt—it has 5 mols of constitutional water. At 19°, the conc. aq. soln. has a sp. gr. 3·36 to 3·37. At 16·2°, 100 parts of water dissolve 306·8 parts of the salt dried at 100°; 299·7 parts at 19·6°, and 286 parts at 21·8°. G. W. A. Kahlbaum and co-workers give for the index of refraction at 20°, $\mu=1·6109$ for the He_β-line, and 1·5981 for the Na-line. D. Klein obtained *nickel borotungstate*, $2NiO.9WO_3.B_2O_3.18H_2O$, in green crystals which melt at 80°, forming a liquid of sp. gr. 3·6; a per cent. soln. has a sp. gr. 3·34. A soln. with 261·6 parts of salt in 100 parts of water has a maximum sp. gr. The sp. gr. of a sat. soln. at 15·75°/4° is 2·2959; and at 15·90°/4°, 2·2956. G. W. A. Kahlbaum and co-workers gave for the index of refraction at 20°, $\mu=1·4946$ for the orange He-line; 1·5037 for the bluish-green He-line; 1·5046 for the blue He-line; and 1·5047 for the He_β-line. These preparations want repeating.

According to C. F. Rammelsberg,[5] the dark green precipitate which borax forms with uranium tetrachloride soln. is almost wholly uranous hydroxide; J. B. Richter obtained a pale yellow *uranyl borate* by treating a uranyl salt soln. with borax. It is sparingly soluble in water.

§ 16. The Borates of Manganese and of the Iron and Platinum Families

According to J. J. Berzelius,[1] borax gives a white precipitate with salts of manganese, and the precipitate is soluble in an aq. soln. of magnesium sulphate; the presence of a magnesium salt prevents the precipitation. Water decomposes the precipitate rapidly, forming manganic oxide. F. Borchers observed similar results with manganous salts as those indicated in connection with zinc salts. L. Joulin found alkali di- and tetra- borates decompose manganese salt soln. slowly and incompletely, while A. Laurent stated that potassium hexaborate gives no precipitate with manganous salt soln. C. Tissier stated that manganous hydroxide is soluble in a boiling soln. of boric acid; and if a manganous salt be treated with an excess of borax, heated to boiling, and then treated with sufficient borax to saturate exactly the acid of the manganous salt, all is dissolved. H. Endemann and J. W. Paisley found that in the presence of water, the reaction between borax and a manganous salt soln progresses until the ratio of MnO : B_2O_3 in the soln. is as 1 : 3, and the precipitate contains a little acid borate. The soln. oxidizes in air. According to W. N. Hartley and H. Ramage, a bulky precipitate was obtained by adding a soln. of manganese sulphate slowly to a soln. of borax at about 22·4° until only a small quantity on the former remained undecomposed. The precipitate was washed by decantation, and when dried in vacuo over sulphuric acid it furnished a bulky brownish-white powder. Analyses corresponded with **monohydrated manganese tetrahydro-orthoborate,** $MnH_4(BO_3)_2.H_2O$, or $MnO.B_2O_3, 3H_2O$; if dried at 100° the composition is $MnH_4(BO_3)_2$:

$$\begin{matrix}HO\\HO\end{matrix}\!>B-O-Mn-O-B<\!\begin{matrix}OH\\OH\end{matrix}$$

The reaction is represented $Na_2B_4O_7+2MnSO_4+5H_2O=Na_2SO_4+H_2SO_4+2MnH_4(BO_3)_2$; at 22·4°, the mother liquid retained 6·26 grms. of $MnH_4(BO_3)_2$ per litre. The same compound was produced by treating borax with sodium hydroxide and manganese sulphate, $Na_2B_4O_7+2NaOH+3H_2O+2MnSO_4=2Na_2SO_4+2MnH_4(BO_3)_2$; at 15°, the mother liquid retains 2·09 grms. of $MnH_4(BO_3)_2$ per litre.

Twenty grms. of borax and 4·2 grms. of caustic soda were dissolved in water and the soln. was boiled for an hour to effect the combination of the base and the salt. The soln. was then cooled, diluted to about 800 c.c., and manganese sulphate soln. added until, on testing the mother liquor with borax soln., a slight precipitate appeared. When 32 c.c. had been added, there was no precipitate, but when 1 c.c. more had been added, a white precipitate slowly formed. The quantity of $MnH_4(BO_3)_2$ in the mother liquor was determined. Manganese sulphate, added to the mother liquor, also caused a precipitate, showing that the manganese borate was less soluble in the soln. thus produced. It was remarked that the precipitate in the manganese sulphate soln. oxidized much more rapidly than in the soln containing an excess of borax. The precipitate retains sodium sulphate with considerable tenacity, and when the quantity of sodium sulphate is decreased by washing, it is to be remarked that the compound oxidizes much more quickly in the greater state of purity.

W. N. Hartley and H. Ramage measured the loss of water which occurs when the salt is heated to different temp., and they found breaks which they interpret to mean that the following compounds are produced: $MnH_4(BO_3)_2.H_2O$ at 22°; $MnH_4(BO_3)_2$ at 100°; $MnH_2B_2O_5$ at 170°; $MnB_2O_4.\frac{10}{11}H_2O$ between 195° and 220°; $MnB_2O_4.\frac{5}{6}H_2O$ at 225°; $MnB_2O_4.\frac{2}{3}H_2O$ between 295° and 305°: $MnB_2O_4.H_2O$ at a red heat; and $Mn(BO_2)_2$ when the salt is partially fused. They also found that the solubility of the borate in water containing a "mere trace" of the borate is 0·94 grm. $MnH_4(BO_3)_2$ per litre at 13·3°; 0·50 grm. at 44°; and 0·08 grm. at 80°; showing that the borate is less soluble at 80° than at a lower temp., and therefore, manganese borate is deposited from a soln. heated to 80°. The phenomenon is attributed to the dehydration of the monohydrate at 80°, a change completed at 100° when the salt is heated in air. Soln. containing 0·266, 0·084, and 0·046 grm. of sodium sulphate per litre between 15·5° and 17°, dissolved respectively 1·60, 1·76, and 1·54 grms. of the borate per litre. Soln. with 20 grms. of sodium sulphate per litre at 18·5°, 40°, 60°, and 80° dissolved respectively 0·77, 0·65, 0·36, and 0·12 grm. of borate per litre; soln. containing 20 grms. of sodium chloride per litre dissolved at 18·2°, 59°, and 80°, respectively 1·31, 0·60, and 0·29 grm. of the borate; and soln. containing 20 grms. of calcium chloride per litre dissolved at 17·6°, 43°, 61°, and 80°, respectively 2·91, 2·44, 2·25, and 1·35 grms. of manganese borate per litre.

Manganese borate is used in the preparation of drying oils, and oil varnishes.[2] Large proportions of calcium sulphate as impurity have been reported.

C. W. Scheele[3] noted that fused borax dissolves manganese oxide, forming a colourless clear glass which becomes opaque on cooling. A. Rosenheim and F. Leyser made complex **manganese pentaborate.** Manganese carbonate was found by W. Guertler to dissolve rapidly in the fused acid with the evolution of carbon dioxide. The molten soln. separates into two layers; the upper colourless layer is mainly boric oxide, the lower layer is dark brown. The powdered mass after extraction with water furnishes crystals of **manganese tetraborate,** $MnO.2B_2O_3$, or MnB_4O_7, and the compound shows some analogies with the corresponding strontium and calcium borates. H. Endemann and J. W. Paisley obtained **pentahydrated manganese tetraborate,** $MnB_4O_7.5H_2O$, by triturating an acid manganese borate with a little water and the calculated proportions of boric acid, and drying the product in air; it was also obtained by adding sodium hydroxide to a soln. of borax so as to furnish 4 mols of $NaBO_2$, and mixing the product with 2 mols of manganous chloride. The precipitate was washed and the right amount of a soln. of boric acid added to convert the precipitate into MnB_4O_7, and the product was dried in air. If dried just below 120°, **trihydrated manganese tetraborate,** $MnB_4O_7.3H_2O$, is formed. This product when mixed with water hardens like plaster of Paris. It loses all its water at a red heat, and loses a little boric oxide as shown by its becoming superficially brown.

L. Ouvrard prepared **manganese orthoborate,** $Mn_3(BO_3)_2$, or $3MnO.B_2O_3$, by heating manganese sulphate or chloride with equi-molar proportions of potassium hydrofluoride and boric oxide. The needle-like crystals are pale brown and, according to E. Mallard, the rhombic crystals have the axial ratios $a:b:c=0·6511:1:0·5311$. J. J. Ebelmen obtained the same compound, and he also reported **manganese sesquiborate,** $3MnO.2B_2O_3$, which E. Mallard said forms rhombic crystals with axial ratios $a:b:c=1·8873:1:2·012$; but W. Guertler thinks that this product is more probably dimanganese diborate, $2MnO.B_2O_3$. W. Guertler also prepared **manganese di- or metaborate,** $Mn(BO_2)_2$, or $MnO.B_2O_3$, by fusing together eq. quantities of the components. W. N. Hartley and H. Ramage made this borate by heating manganese tetrahydro-orthoborate to incipient fusion. G. J. Brush described a mineral *sussexite*, found in the zinc mine at Sussex, New Jersey. G. J. Brush's and S. L. Penfield's analyses correspond with (Mn, Mg, Zn)$H.BO_3$, or [(Mn, Mg, Zn)OH]BO_2.

B_2O_3	MnO	MgO	ZnO	H_2O
32·60	39·09	16·47	3·24	9·06

The mineral occurs in fibrous masses coloured white or yellow; the sp. gr. is 3·42; and the hardness 3. It is soluble in hydrochloric acid. The mineral *pinakiolite* was found by G. Flink in the manganese mine at Langbanshyttan, Sweden, and named after *πινάκιον*, a small board, and *λίθος*, stone. Analyses by G. Flink, and H. Bäckström correspond with $(MgO)_3.B_2O_3.MnO.Mn_2O_3$; W. C. Brögger assigns to it the formula $Mg_2O.MnO.BO_3$, or $Mg_2O.MnO_2.BO_2$.

$$O\begin{cases}Mg—O—B{=}O\\Mg—O—Mn{=}O\end{cases}$$

The rhombic plates have the axial ratios $a:b:c=0·83385:1:0·58807$; the sp. gr. is 3·881; and the hardness 6. The mineral is dark brown, almost black. It is almost opaque in the direction of the c-axis; dark reddish-brown in the direction of the b-axis; and reddish-yellow in the direction of the a-axis. Dil. acids have very little action. It is soluble in conc. hydrochloric acid.

J. Percy[4] fused mixtures corresponding with $FeO:B_2O_3$, $3FeO:B_2O_3$, $3FeO:2B_2O_3$, and $6FeO:B_2O_3$, and obtained brownish-black vitreous products, but no evidence of the formation of definite borates. C. W. Scheele prepared a pale yellow powder of **ferrous borate** by double decomposition with borax and a ferrous salt soln. ; J. Tünnermann likewise obtained a green product. It was fusible before the blowpipe, and hydrolyzed by water. W. Guertler could not make ferrous borate by fusing ferrous oxide with boric acid, oxidation always occurred even when the fusion took place in a stream of hydrogen. The product separates on cooling into two layers. The upper black layer is a soln. of iron oxide in boric oxide ; the lower layer contained crystals of $2FeO.2Fe_2O_3.3B_2O_3$. J. Percy heated mixtures corresponding with $Fe_2O_3.B_2O_3$ and $Fe_2O_3 : 3B_2O_3$, and obtained vitreous products but no evidence of combination ; part at least of the ferric oxide was reduced to a lower oxide. H. Rose obtained a voluminous yellow insoluble precipitate of **ferric borate** by the action of borax on a soln. of a ferric salt. The colour darkens when it is heated. G. Rousseau and H. Allaire prepared cubic crystals of **ferrous chloroborate,** $6FeO.8B_2O_3.FeCl_2$, by passing the vapour of ferrous chloride over iron wire and calcium borate in a stream of carbon dioxide at 330°.

The dark green mineral *ludwigite* is a magnesium ferric borate ; specimens from Morawitza were described by G. Tschermak, A. Veszely, J. E. Whitfield, and V. von Zepharovich ; W. T. Schaller described a sample from Philipsbury, Montana. The last-named represented its composition by $FeO.Fe_2O_3.3MgO.B_2O_3$; J. J. Ebelmen synthesized a related product of sp. gr. 3·85 by melting together 26 grms. of ferric oxide, 20 grms. of magnesia, and 25 grms. of boric oxide. It is possible that a magnesium ferrimagnesium borate, $MgO.Fe_2O_3.3MgO.B_2O_3$, and a ferrous ferrimagnesium borate, $FeO.Fe_2O_3.3MgO.B_2O_3$, are in isomorphous admixture. The idealized compound is also regarded as a **magnesium boratoferrite,** $Mg_2O.FeO_2.BO_2$. The rhombic crystals have the axial ratios $a : b : c = 0·988 : 1 : –$. E. Mallard also measured the prism angles A. F. Renard made observations on the crystals. The sp. gr. is 3·907–4·016 ; and the hardness is 2. G. Tschermak found that ludwigite melts to a black magnetic slag. Cold dil. hydrochloric acid slowly dissolves the fine powder while the warm acid acts rapidly ; sulphuric acid also dissolves the mineral slowly, forming a green soln., and, according to F. Berwerth, ludwigite is converted into limonite. A. S. Eakle also found black prismatic crystals of a mineral at Riverside, California, and they called it *vonsenite*. Its structure and optical properties differ from ludwigite. Its composition approximates to $3(Fe, Mg)O.B_2O_3 + FeO.Fe_2O_3$. The mineral is either rhombic or monoclinic with the axial ratios $a : b : c = 0·7558 : 1 :$—the sp. gr. is 4·21, and the hardness 5. It is quite soluble in hydrochloric or sulphuric acid.

W. Guertler[5] melted a mol of cobalt with 3 mols of boric oxide, and obtained a glass which separated into two layers ; the upper blue layer was mainly boric oxide ; the lower layer furnished violet acicular crystals which could be isolated by washing out the boric oxide. The composition corresponded with **cobalt diborate,** $2CoO.B_2O_3$, or $Co_2B_2O_5$. L. Ouvrard also made a compound with the same composition by treating cobalt chloride with a mixture of equi-molar proportions of boric oxide and potassium hydrofluoride. The violet prismatic crystals were isolated by washing with water. E. Mallard assumed the existence of $3CoO.2B_2O_3$, isomorphous with the corresponding magnesium compound ; and when the latter was shown to be $2MgO.B_2O_3$, the former was taken to be best represented by $2CoO.B_2O_3$. L. Ouvrard also made rose-violet crystals of **cobalt orthoborate,** $3CoO.B_2O_3$, or $Co_3(BO_3)_2$, by using less boric oxide than was employed for the preceding. E. Mallard said that the rhombic crystals have the axial ratio $a : b = 0·641$. A. Rosenheim and F. Leyser made complex **cobalt pentaborate.** A. Ditte made **decahydrated cobalt tetraborate,** $CoO.2B_2O_3.10H_2O$, by mixing a cold soln. of borax with one of a cobalt salt ; and **dodecahydrated cobalt octoborate,** $CoO.4B_2O_3.12H_2O$, in rose-red crystals ; by evaporating a sat. soln. of cobalt carbonate in boric acid. H. Rose reported a rose-coloured amorphous **tetrahydrated tricobalt tetraborate,** $3CoO.2B_2O_3.4H_2O$, to be formed when a soln. of borax is added to one of a cobalt salt. J. J. Ebelmen, and E. Mallard studied the **cobalt magnesium borate,** $2B_2O_3(CoO,MgO)_3$, which is obtained in triclinic crystals from a molten mixture of the components. J. J. Ebelmen's $2(CoO.MgO).B_2O_3$ is assumed by E. Mallard to be isomorphous with $2CoO.B_2O_3$ and $2MgO.B_2O_3$. R. Tupputi obtained a pale apple-green powder by adding borax to a soln. of a nickel salt; the precipitate is insoluble in water but soluble in the three mineral acids. J. J. Berzelius said that the product fused to a hyacinth-coloured glass. According to W. Guertler, nickel oxide behaves like cobalt oxide towards fused boric oxide, and he obtained crystals of **dinickel diborate,** $2NiO.B_2O_3$. L. Ouvrard obtained green crystals of **nickel orthoborate,** $3NiO.B_2O_3$, or $Ni_3(BO_3)_2$; of **hexahydrated nickel tetraborate,** $NiO.2B_2O_3.6H_2O$; and of **decahydrated nickel octoborate,** $NiO.4B_2O_3.10H_2O$, analogous to the cobalt borates.

Soln. of rhodium salts give a precipitate—probably *rhodium borate*—with sodium borate.

§ 17. Perboric Acids and the Perborates

The existence of perborates was demonstrated by A. Étard[1] in 1880; by mixing a sat. soln. of boric acid and hydrated barium peroxide, he obtained a product which possessed oxidizing properties, liberating chlorine from hydrochloric acid, and giving oxygen with dil. acids. In 1898, S. M. Tanatar produced sodium perborate by the action of hydrogen dioxide on a soln. of sodium orthoborate. P. G. Melikoff and L. Pissarjewsky in 1898 prepared the potassium and sodium salts. *Perboric acid* itself has not been made. L. Pissarjewsky said that at 25° aq. soln. of boric acid and hydrogen peroxide do not combine, but in ethereal soln. and an excess of hydrogen peroxide, the partition coeff. of boric acid increases a little corresponding with the formation of free perboric acid in the etheral soln. As a typical perborate, consider ordinary **sodium perborate,** $NaBO_3.4H_2O$. P. G. Melikoff and L. Pissarjewsky made it by treating a sat. soln. of borax containing an eq. amount of sodium hydroxide with double the amount of hydrogen peroxide required for the production of the perborate. After some time, crystals of the salt separate: $Na_2B_4O_7+2NaOH+4H_2O_2=5H_2O+4NaBO_3$.

According to F. H. Fuhrmann, the introduction of catalytic metallic compounds in the liquid is avoided by using wooden vats and stirrers, and all metal pipes, taps, etc., are well tinned. The product is best separated from the mother liquid centrifugally; and the salt is dried by passing it through an apparatus where it meets a current of air which may be heated to 50°.

The two modern methods used in the manufacture of sodium perborate are: (i) the interaction of sodium dioxide and sodium metaborate; and (ii) electrolytic methods. Hinkel et Cie. suggest the auto-oxidation of aq. soln. of borax and lime by means of aluminium amalgam in a current of oxygen. J. Bruhat and H. Dubois obtained it by adding alcohol to a soln. of sodium orthoborate with twice the calculated quantity of hydrogen peroxide. O. T. Christensen cooled a soln. of 62 grms. of boric acid in 500 c.c. of water, and added 87 grms. of sodium peroxide in small portions at a time so that the temp. did not rise over 30°. Next day, 45 grms. of crystals of the perborate separated out. G. F. Jaubert added enough mineral acid to a soln. of perborate to neutralize about half the contained alkali, and crystallized the soln.

S. M. Tanatar stated that perborates are produced at the anode during the electrolysis of conc. soln. of sodium orthoborate, but E. J. Constam and J. C. Bennett did not confirm this. J. Bruhat and H. Dubois, however, confirmed S. M. Tanatar's observation, and E. A. Pouzenc patented a process for making sodium perborate by electrolysis. The mechanism of the electrolysis has not been established. S. M. Tanatar assumed that the borate is oxidized by the hydrogen peroxide formed at the anode. The hydrogen peroxide would be produced by the discharge of OH′-ions contained in the soln. of sodium orthoborate. E. J. Constam and J. C. Bennett objected that the soln. of hydrogen peroxide under such conditions is too dil. for the conversion of borates to perborates. The latter objection does not allow for a possible local conc. of the hydrogen peroxide at the anode sufficient for the purpose. E. H. Reisenfeld and B. Reinhold could not obtain hydrogen peroxide by electrolysis of soln. of sodium hydroxide, but they did obtain it in the presence of potassium hydroxide. The Fredrikstad elektrokemiske Fabrik claims that in the preparation of perborates by the usual electrolytic process, a large percentage of electrical energy and borax is wasted, only highly purified borax can be used, and it is difficult to maintain a constant and continuous production. The last-named disadvantages are overcome by adding sodium cyanide to the borax soln. This prevents the decomposition of the perborate formed in the soln. When the soln. is sat., sodium peroxide is added, and the perborate then crystallizes out. The Deutsche Gold- und Silberscheideanstalt add fluorides or perchlorates to increase the anode potential. The subject has been investigated by T. Valeur, and P. C. Alsgaard. K. Arndt's electrolytic process is as follows:

A soln. of 40 grms. of borax and 120 grms. of anhydrous sodium carbonate is electrolyzed between a platinum gauze anode and a cathode made of tin tubing bent in a zigzag form round the anode. A current of water is circulated through the cathode, whereby the temp. is kept below 18°. A current of 20 amps. at 6 volts is used with an anode 8 × 6 cms. After an hour the current is stopped and the soln. cooled, when about 20 grms. of sodium perborate separate out in small crystals. These are washed with a little ice-cold water and dried. A somewhat better yield can be obtained if 0·1 grm. of sodium chromate and 1 drop of turkey-red oil are added to the soln. For the preparation of soln. of sodium perborate for bleaching purposes, it is recommended that the anode should be smeared with vaseline. In these circumstances, a yield of 27 grms. per litre can be very efficiently obtained.

Sodium perborate forms transparent monoclinic prisms of the *tetrahydrate*, and, according to J. Bruhat and H. Dubois, if the tetrahydrate be dried, it furnishes the *monohydrate*, and in vacuo, over phosphorus pentoxide, the anhydrous salt is formed. F. Förster prefers to regard the tetrahydrate as a salt, $NaBO_2.H_2O_2.3H_2O$, than as $NaBO_3.4H_2O$. When the salt, after dehydration at 50°–55°, is further heated at 120° in a vacuum, it loses water, and the residue, which evolves oxygen on treating with water, consists chiefly of $(NaBO_2)_2O_2$ with some $NaBO_2.H_2O$ and metaborate. This compound, $(NaBO_2)_2O_2$, has properties which differ from those of $NaBO_3$, and this tends to imply the existence of a substitution product of hydrogen peroxide of the composition $ONa.B{<}^{O}_{O}$, analogous to persulphates and percarbonates. This is confirmed by the fact that sodium perborate has been electrolytically prepared. Sodium perborate, obtained by the action of hydrogen peroxide on the metaborate, behaves as the salt of an acid of greater strength than boric acid. The salt is stable in air; and G. F. Jaubert stated that the salt is not affected by atm. carbon dioxide, whereas, S. M. Tanatar found it is rapidly decomposed by that gas. The solubility of the salt in water has been measured by P. G. Melikoff and L. Pissarjewsky, S. M. Tanatar, and G. F. Jaubert and G. Lion. The latter found that 100 c.c. of water at 15° dissolve 2·55 grms. of the tetrahydrated salt at 21°, 2·69 grms.; at 26°, 2·85 grms.; and at 32°, 3·78 grms. J. Bruhart and H. Dubois found that the solubility is increased in the presence of boric tartaric or citric acid, or of glycerol, while G. F. Jaubert and G. Lion found that the solubility is increased in the presence of small proportions of magnesium and ammonium sulphates. G. F. Jaubert noticed that the temp. is lowered when the salt is dissolved in water, and S. M. Tanatar gave −11·564 Cals. for the heat of soln. in water at 16·1°; and −8·950 Cals. for the heat of soln. in $\frac{1}{2}N$-sulphuric acid at 17·29°; so that the heat of decomposition of the dissolved salt by sulphuric acid is 2·614 Cals.

The aq. soln. has an alkaline reaction, and it is stable at ordinary temp. L. Pissarjewsky measured the distribution coeff. of hydrogen peroxide between aq. and ethereal soln. of borates, and found the relative conc. of the borates in the ether phase increased in conformity with the assumption that the soln. contains perborates. He further showed that at least 60 per cent. of the peroxide oxygen in an aq. soln. of sodium perborate, at 25°, is hydrogen peroxide; and at this temp. he inferred that sodium perborate does not exist in aq. soln., but hydrolyzes: $NaO_2BO+H_2O=NaO_2H+HBO_2$; and in accord with the experiments of H. T. Calvert, he assumed that the sodium hydroperoxide thus formed hydrolyzes into hydrogen peroxide and sodium hydroxide. The latter unites with the boric acid so that the aq. soln. contains sodium borate, boric acid, sodium hydroperoxide, hydrogen peroxide, sodium hydroxide, and traces of sodium perborate. At lower temp., sodium perborate is formed, $NaO_2H+HO.BO=H_2O+NaO_2BO$, in increasing proportions the lower the temp., so that at 0° only sodium perborate is present. This is in agreement with the measurements of E. J. Constam and J. C. Bennett on the electrical conductivity of aq. soln. of sodium perborate. The conductivity at a dilution $v=32$ is 30·7, and for $v=1024$, 40·1, so that, according to Ostwald's rule, the acid is monobasic, and the formula of the sodium salt is $NaBO_3$, and not $Na_2B_2O_6$. H. Menzel measured the effect of hydrogen dioxide on the f.p. and electrical conductivity of soln. of orthoboric acid, and on soln. of alkali metaborate, and borax. He also measured the partition coeff. of hydrogen dioxide between amyl alcohol and aq. soln. of potassium metaborate. For the equilibrium $(BO_2.H_2O_2)' \rightleftharpoons BO_2'+H_2O$, where $[(BO_2.H_2O_2)']K=[BO_2'][H_2O_2]$, he found $K=0·024$ at 0°, and 0·033 at 18°; for $HBO_2+H_2O_2 \rightleftharpoons (HBO_2.H_2O_2) \rightleftharpoons H^{\cdot}+(BO_2.H_2O_2)'$, he found $[HBO_2][H_2O_2]K=[H^{\cdot}][(BO_2.H_2O_2)']$, $K=2\times10^{-8}$ at 18°; and for $HBO_2 \rightleftharpoons H^{\cdot}+BO_2'$, $[HBO_2]K=[H^{\cdot}][BO_2']$, $K=5·7\times10^{-10}$. In conc. soln. of metaborates and borax to which hydrogen dioxide has been added, there is a great reduction of alkalinity and affinity due to the formation of complex acids, a fact which explains the evolution of carbon dioxide from mixtures of borax and hydrocarbonate on the addition of hydrogen dioxide.

The hydrolysis of the perborate in aq. soln is in agreement with the constitution $HO.O.B:O$, and the reaction: $O:BO.OH+2H_2O=B(OH)_3+HO.OH$. E. Bosshard and H. K. Zwicky do not agree with this. They found that when a soln. of an alkali perborate is gently distilled under press. at 50°–60°, or in a stream of dry air free from carbon dioxide, no hydrogen peroxide is found in the distillate; water is lost, and the percentage of active oxygen in the residue increases. They infer that in perborates the active oxygen cannot be represented as hydrogen peroxide of crystallization, and that sodium perborate has the constitution

$$NaO.B{<}^{O}_{O}$$

This view is supported by the fact that a stable potassium hyperborate, $KBO_4.H_2O$, is known which evolves only traces of oxygen when dissolved in water. When dried over phosphorus pentoxide in vacuo, $4KBO_4.H_2O$ is produced so that the hyperborate cannot be formulated $KBO_3.H_2O_2$, but is rather a derivative of potassium hyperoxide and perboric acid, and it may be represented

$$KO.O.B{<}^{O}_{O}$$

This compound is stable, but if its constitution were $KO.O.OBO$, analogies indicate that it would be unstable.

According to P. G. Melikoff and L. Pissarjewsky, the aq. soln. of sodium perborate begins to decompose at 40° giving off oxygen. U. Sborgi and G. Nocentini found that the decomposition of sodium perborate in aq. soln at different temp. does not obey any simple law, although it corresponds approximately with a unimolecular reaction, the values of the equilibrium constant lying on a regular curve which passes through a maximum. The velocity of the reaction is influenced in one direction or the other by the decomposition products of the perborate and by a number of other substances. E. Bosshard and H. K. Zwicky found the velocity of decomposition of aq. soln. under the catalytic influence of colloidal platinum is smaller than that of a soln. of hydrogen peroxide under similar conditions; and with dil. sulphuric acid it forms hydrogen peroxide; G. F. Jaubert found that if the powdered salt be added to 50 per cent. sulphuric acid, boric acid is precipitated and a soln. of hydrogen peroxide is formed. According to O. T. Christensen, with conc. sulphuric acid, ozonized oxygen is evolved; the soln. possesses oxidizing properties, it liberates chlorine from hydrochloric acid; it oxidizes ammonium sulphide with the evolution of much heat. The soln. gives off oxygen when treated with solid or soln. of iodine, or with bromine water; it gives a precipitate with mercurous nitrate soluble in excess, and when the soln. is warmed mercury is precipitated; mercuric chloride gives a reddish-yellow or brown precipitate containing free mercury; mercuric oxide is reduced; auric chloride furnishes brown gold; platinum tetrachloride does not react at ordinary temp.; palladium tetrachloride gives oxygen; cupric sulphate gives a yellowish-green precipitate which is soon decomposed; neutral lead acetate gives a yellowish-white precipitate, and basic lead acetate a dark brown precipitate; lead dioxide gives oxygen; manganous salts form manganese dioxide with the evolution of oxygen; cobalt nitrate gives a precipitate which soon decomposes with the evolution of oxygen; chromic acid and ether, or chromates with an acid, give the perchromate reaction; it converts ferrous to ferric salts; morphine hydrochloride gives a colourless acicular precipitate which soon dissolves with the evolution of oxygen; and quinine sulphate and strychnine nitrate also give white precipitates. Thus J. Bruhat and H. Dubois have shown, the aq. soln. has properties characteristic of soln. of hydrogen peroxide. According to A. Monnier, a dil. soln. of titanochloride gives a reddish tinge with perborates; and no coloration or precipitate with a 0·5 per cent. alcoholic soln. of benzidine. Perborates with a soln. of chrome alum give a greenish-yellow precipitate, which when shaken with a little ether and dil. sulphuric acid, furnishes a blue ether extract. This distinguishes perborates from percarbonates and hydrogen dioxide. Both perborates and percarbonates impart a blue coloration to a soln. of potassium dichromate acidified with sulphuric acid.

The active oxygen in perborates is determined by titrating the acid soln. with potassium permanganate soln. E. K. Farrar, E. Rupp and J. Mielck, A. Skrabal and J. P. Vacek, and W. Lenz and E. Richter have discussed this problem. J. M. Mathews emphasized that the bleaching is due to the hydrogen peroxide which is formed when the salt is dissolved in water; and while sodium perborate furnishes about 10·4 per cent. of active oxygen, sodium peroxide gives twice as much. The cost of bleaching with the former is expensive, out of all proportion when compared with the latter. The advantage with sodium perborate is that the bleaching soln. can be used with hot soln. Indeed, hot water is required for the complete decomposition. The particular advantage of the perborates over hydrogen peroxide is due to the fact that they can be employed in various scouring mixtures to be used by the laundry in hot soln. For example, the perborates of sodium and magnesium are used industrially for bleaching purposes. Not only is sodium perborate used as a bleaching agent in the textile industries; and as a detergent in place of sodium peroxide, but it also enters into the composition of deodorants, germicides, decolorizing agents, antiseptics, dentifrices, and various pharmaceutical preparations. Well-crystallized sodium perborate preserves its strength and is now manufactured on a commercial scale, and it may replace hydrogen and sodium peroxides in the various industries. It has the advantage over hydrogen peroxide of being highly stable, and being a solid it is more easily and economically transported. Sodium perborate can be incorporated with soaps and washing powders to furnish a combined washing and bleaching agent; such preparations are *persil*—a mixture of soap, soda ash, sodium silicate, and perborate; *clarax*—a mixture of borax, sodium phosphate, and perborate; *ozonite*—a mixture like persil with different proportions of the same constituents; and *perborin* products. *Perborin-M* is a mixture of soap, perborate, and alkali. Perborin is a trade-name for sodium perborate.

O. T. Christensen prepared potassium perborate by a process similar to that employed for the sodium salts, but the constitution was not very clear; it may be $2KBO_3.KBO_4.5H_2O$, or $3KBO_3.H_2O_2.4H_2O$. C. F. von Girsewald and A. Wolokitin obtained **hemihydrated potassium perborate,** $2KBO_3.H_2O$, by adding 100 c.c. of a cold 95 per cent. soln. of potassium metaborate to 1020 c.c. of a cold 3 per cent. soln. of hydrogen peroxide. The filtered liquid was treated with 900 c.c. of methyl alcohol. The microcrystalline powder was washed with ice-cold water. The salt is stable when dry, but an aq. soln. at 50° loses its active oxygen in an hour, and more slowly at lower temp. 100 parts of water dissolve 1·25 parts of the salt at 0°, and 2·5 parts at 15°. The white powder is stable at ordinary temp., and it has a composition and properties corresponding with **potassium perborate hemiperoxyhydrate,** $2KBO_3.H_2O_2$. When rapidly heated, it deflagrates at 150°–160°, but if heated slowly, the active oxygen is quantitatively evolved. O. T. Christensen prepared **rubidium perborate,** $RbBO_3.H_2O$, by warming 20 grms. of rubidium hydroxide with 40 c.c. of water and 12 grms. of boric acid, and treating the cold soln. with 110 c.c. of 6 per cent. hydrogen peroxide, and then with an equal vol. of 96 per cent. alcohol. The oily precipitate was then allowed to crystallize. The properties of the salt resembled those of sodium perborate. He also made **cæsium perborate,** $CsBO_3.H_2O$, in a similar manner. P. G. Melikoff and L. Pissarjewsky prepared **hemihydrated ammonium perborate,** $2(NH_4)_2BO_3.H_2O$, by dissolving boric acid in 2·5 per cent. hydrogen peroxide, adding aq. ammonia, and then alcohol, when colourless isotropic crystals of the trihydrate are deposited. When kept 24 hrs. over conc. sulphuric acid, the hemihydrate is formed; and, according to E. J. Constam and J. C. Bennett, the salt is completely dehydrated over phosphorus pentoxide. S. M. Tanatar has described a monohydrate.

P. G. Melikoff and L. Pissarjewsky prepared **cupric perborate,** $Cu(BO_3)_2$, by adding a sat. soln. of sodium perborate at 0° to a cupric salt. The salt is readily decomposed by water. If silver nitrate be treated with sodium perborate a white curdy precipitate of an impure **silver perborate** is formed. A. Étard prepared **barium perborate** by the action of a soln. of barium peroxide on boric acid. The white amorphous precipitate was stated to be insoluble in water, and to lose a mol of water at 100°, and not to be decomposed by water. The product is hygroscopic, but not deliquescent; it gives off oxygen with acids, and with conc. hydrochloric acid at 40°, chlorine is evolved. J. Bruhat and H. Dubois noted that soluble perborates give a white precipitate when added to a barium salt soln. According to P. G. Melikoff and L. Pissarjewsky the white flocculent precipitate has the composition $Ba(BO_3)_2.7H_2O$. The corresponding **strontium perborate** and **calcium perborate** were prepared in a similar manner. The calcium salt is said to be sparingly soluble in water and to be decomposed by water more quickly than the barium salt. H. Byk obtained a 90 per cent. yield of calcium perborate by treating a soln. of 11 parts of crystallized calcium chloride in 10 parts of water with 15·4 parts of sodium perborate at 50°–60°.

A. Étard, and J. Bruhat and H. Dubois prepared **magnesium perborate,** but the composition was not constant presumably because of hydrolysis. The Deutsche Gold- and Silberscheide Anstalt prepared a white amorphous magnesium perborate by the action of sodium peroxide and boric acid on a magnesium salt. When dry the salt is stable, but with water there is formed an aq. soln. of an acid perborate, and a precipitate of a basic perborate. The corresponding **zinc perborate** was similarly prepared. H. Buchtala prepared **thallous perborate,** $Tl_2B_2O_7$, as a white powder by adding 30 per cent. of hydrogen peroxide to an aq. soln. of one of the thallous borates. The aq. soln. decomposes on evaporation, forming thallous metaborate. The salt exhibits the usual reactions of a per-salt, and explodes when heated rapidly. The graphic formula is written:

$$\begin{matrix}\text{TlO.B.O.O}\\ \text{TlO.B.O.O}\end{matrix}>\text{O}$$

Unstable **nickel perborate,** and **cobalt perborate** were obtained by P. G. Melikoff and L. Pissarjewsky. By the action of a soln. of a perborate on uranium dioxide, J. Bruhat and H. Dubois prepared a yellow, stable, **uranyl perborate,** $(UO)BO_3$.

G. F. Jaubert claimed to have made **sodium pertetraborate,** $Na_2B_4O_8.10H_2O$, or *perborax* by crystallization from a soln. of 248 grms. of boric acid, and 78 grms. of sodium peroxide in 2 litres of cold water. The salt decomposed into hydrogen peroxide when dissolved in water, and the soln. has an alkaline reaction. The first crop of crystals is richer in active oxygen than those separating later, and the last fraction contains no active oxygen at all; and ordinary sodium perborate crystallizes out if the aq. soln. is mixed with hydrochloric acid eq. to half the sodium in the perborate. 100 grms. of water at 11°, 22°, and 32° dissolve respectively 4·2, 7·1, and 13·8 grms. of salt. J. Bruhat and H. Dubois prepared what they regarded as **potassium perdiborate,** $KB_2O_5.2H_2O$, by adding alcohol to a soln. of potassium diborate in hydrogen peroxide. The crystals lose a mol of water in vacuo over phosphorus pentoxide.

P. G. Melikoff and L. Pissarjewsky obtained indications of the formation of **sodium hyperborate,** $NaO.BO_3$, or $NaBO_4$, but the salt was not isolated. E. Bosshard and H. K. Zwicky prepared **potassium hyperborate,** $KBO_4.H_2O$, which evolves only traces of oxygen when dissolved in water—*vide supra*. G. I. Petrenko prepared an **ammonium hyperborate,** $NH_4BO_3.NH_4BO_4.2H_2O$, by the action of hydrogen peroxide on ammonium perborate, and precipitation with alcohol at a low temp. A monohydrate was also prepared.

§ 18. Boron Fluoride

J. L. Gay Lussac and L. J. Thénard [1] heated a mixture of vitreous boric oxide with twice its weight of fluorspar free from silica to whiteness in an inclined iron tube, and obtained *le gas fluoborique*, **boron trifluoride**, BF_3. J. Davy obtained the same gas by heating in a glass flask a mixture of 12 parts of sulphuric acid, one of vitreous boric oxide, and two of fluorspar; G. Ferrari, and S. G. Rawson used a similar process for these three constituents. According to J. J. Berzelius, the gas obtained by this method contains a large quantity of silicon fluoride, derived from the silica in the fluorspar and in the glass. The gas can be freed but imperfectly from the silicon fluorides by scrubbing with vitreous boric oxide. H. Schiff, and F. Stolba made the gas by heating a mixture of potassium fluoborate, KBF_4, with 15–20 per cent. of fused and pulverized boron trioxide and conc. sulphuric acid. O. Ruff recommended heating a mixture of equal parts of boron trioxide and cryolite free from silica, with conc. sulphuric acid.

H. Moissan found that boron trifluoride is formed when fluorine is treated with an excess of boron; by the action of phosphorus trifluoride on boron; by the action of silver fluoride on cold boron iodide; and when fluorine acts on boron chloride; A. Étard, by the action of hydrofluoric acid on barium perborate; L. Ouvrard, by heating potassium hydrofluoride, KHF_2, and boric oxide with metallic oxides; and L. Moser and W. Eidmann, by heating boron nitride with sodium fluoride and sulphuric acid; ammonium sulphate and boron fluoride are formed. H. Giebelhausen found that amorphous boron reacts with fused cadmium fluoride, forming cadmium and boron trifluoride. E. Berger made boron trifluoride from a mixture of lead fluoride, calcium boride, and alkali nitrate.

Boron trifluoride is a colourless gas, with a pungent, suffocating odour. It is stable and non-combustible and a non-supporter of combustion. In moist air it gives dense white fumes. Its **vapour density,** determined by J. Davy, T. Thomson, and J. B. A. Dumas—2·3124-2·3709—corresponds with the formula BF_3. M. Faraday found that the gas is not liquefied when cooled by the ordinary carbon dioxide bath, but that it forms a limpid, colourless, clear liquid, as mobile as hot ether, when cooled by carbon dioxide under an air pump. He found the approximate **vapour pressures** of the liquid are :

	−52·2°	−54·4°	−57·8°	−63·3°	−73·3°
Vap. press. . . .	11·54	10·00	9·23	7·50	4·61 atm.

According to H. Moissan, boron trifluoride solidifies to a white mass at −160°, and when the gas is purified from hydrogen fluoride by scrubbing with sodium fluoride, its **boiling point** is −101°, and its **melting point** −127°. R. W. Millar calculated the **specific heat,** C_p, to be 11·70 at 278° K., and 10·00 at 189° K. H. Hammerl and M. Berthelot gave 234·8 Cals. for the **heat of formation** of fused BF_3 from amorphous boron.

M. Berthelot found that the gas is not changed by the silent electric discharge, and H. Moissan found that the vol. of the gas remains constant after the passage of electric sparks, and that the walls of the glass containing vessel are not attacked. J. M. Seguin found that the sparking boron trifluoride furnishes a spectrum showing a blue line due to fluorine ; he also found that a mixture of **hydrogen** and boron trifluoride is decomposed by electric sparks. J. Davy found that **water** at ordinary temp. absorbs about 700 times its vol. of boron trifluoride to form a syrupy liquid. According to J. L. Gay Lussac and L. J. Thénard, water absorbs about the same vol. of boron trifluoride as of hydrogen chloride ; the absorption is rapid, and is attended by the evolution of heat. According to H. Hammerl, the soln. of a mol of the gas in water develops 24·51 Cals. A. Basaroff said that water at 0° and 762 mm. press. absorbs 1057 times its vol. of the gas. J. Davy found that **sulphuric acid** absorbs about 50 vols. of the gas. Boron trifluoride should be collected over mercury. According to J. Davy, equal vols. of **ammonia** and boron trifluoride unite to form a white solid which in a closed vessel can be sublimed unchanged. It is probably **boron monammino-trifluoride,** $B(NH_3)F_3$. W. G. Mixter made it by passing boron trifluoride into dried ammonia, and he gave 23 for the vapour density at 19·4°, 754·8 mm. press. and 23·1, at 24·6° and 765·9 mm. press.—theoretical value for a mixture of equal vols. of the component gases is 21·3. He also noticed that the vapour attacks glass. J. Davy found that it is decomposed by a trace of moisture into ammonium oxyfluoborate, and boric acid, and when dissolved in water J. J. Berzelius and J. Davy noted the formation of oxyfluoborate. J. Davy also found that one vol. of boron trifluoride unites with two and with three vols. of ammonia, producing in the former case **boron diammino-trifluoride,** $B(NH_3)_2F_3$, and in the latter case **boron triammino-trifluoride,** $B(NH_3)_3F_3$. In conformity with the so-called ammines of the other boron halides, these products may prove to be mixtures of ammonium fluoride and boronamide. According to A. Besson, boron trifluoride does not unite with **phosphine** at ordinary temp., but combination begins at −30° and at −50° a white solid is obtained, which becomes yellow as the temp. rises, with evolution of 2 vols. of boron fluoride and 1 vol. of hydrogen phosphide, the latter being mixed with some free hydrogen, whilst some solid hydrogen phosphide is formed. The white solid is a **boron hemiphosphinofluoride,** $PH_3.2BF_3$, and is decomposed by water with the evolution of hydrogen and hydrogen phosphide. A. F. O. Germann and M. Cleaveland studied the f.p. of binary mixtures of boron trifluoride with methyl ether, and methyl chloride. They found a compound $BF_3.(CH_3)_2O$ is formed.

According to J. L. Gay Lussac and L. J. Thénard, when **potassium** or **sodium** is heated with boron trifluoride, the metal is covered with a black crust, and burns with a reddish flame; water extracts potassium fluoride or fluoborate from the cold residue, and boron remains, $3K+4BF_3=3KBF_4+B$, or $3K+2BF_3=KBF_4+2KF+B$. S. G. Rawson also studied the reaction with potassium. L. J. Thénard found that **iron** is without action on boron trifluoride at a red heat. J. Davy found **calcium oxide** rapidly absorbs boron trifluoride especially if warmed, forming a fusible mass which gives off the original gas when treated with sulphuric acid: $4CaO+8BF_3=Ca(BO_2)_2+3Ca(BF_4)_2$. A. Baudrimont found that when passed over **red lead** a yellowish-brown gas is produced which smells of chlorine and burnt sugar; decolorizes indigo; does not attack glass; but unites with gold.

§ 19. Hydrofluoboric and Boratofluoric Acids

According to J. L. Lussac and L. J. Thénard,[1] when boron trifluoride is passed into a sufficiently large proportion of cold water, the absorption is rapid, and a colourless fuming syrupy liquid is produced. The boron fluoride is best passed through a tube dipping under mercury which is covered with water, for if the end of the tube dips directly into water, the rapid absorption of the gas would cause the liquid to regurgitate into the generating apparatus. J. Davy showed that water at ordinary temp absorbs 700 vols. of this gas. The soln. then has a sp. gr. 1·770; it gives off unchanged about one-fifth of the absorbed boron fluoride; and, after that, the b.p. rises much above 100°. The boric acid simultaneously formed in the reaction: $4BF_3+3H_2O=3HBF_4+B(OH)_3$, is said to separate as metaboric acid. When the reaction occurs in the presence of an excess of water, H. Hammerl gives 98·04 Cals. for the thermal value. J. J. Berzelius obtained a similar liquid by dissolving boric acid in cold conc. hydrofluoric acid, concentrating the soln. over a water-bath, boiling until it evolves white fumes, and allowing the product to remain over conc. sulphuric acid. The liquid thus obtained has a sp. gr. 1·586. F. C. Mathers and co-workers made an alcoholic soln. of fluoboric acid by adding about 35 grms. of boric acid, free from sodium, to 100 grms. of 48 per cent. hydrofluoric acid—the boric acid was added until a test portion gave no precipitate with lead nitrate. The cold soln. is mixed with an equal volume of alcohol. The liquid can be preserved in wax, rubber, lead, or paraffin bottles, and used as precipitant for sodium in the presence of potassium and magnesium.

According to J. J. Berzelius, the composition of the liquid obtained by the action of hydrofluoric acid on boric acid is in agreement with $H_2B_2O_4.6HF$, and it is decomposed by an excess of water with the precipitation of boric acid and the formation of an aq. soln. of hydroborofluoric acid, $FH.BF_3$. J. J. Berzelius regarded the acid liquor as a definite compound which may be called **boratofluoric acid;** he stated that the aq. soln. of the acid distils unchanged; and that when neutralized with an alkali, it forms a series of **boratofluorides,** $M_2B_2O_4.6MF.H_2O$. These statements and assumptions are probably wrong. The evidence for the individuality of boratofluoric acid is not satisfactory; for when distilled, the different fractions differ in sp. gr. and in composition; the re-crystallization of the salts gives first the alkali fluoride and then a mixture of alkali fluoride and alkali metaborate; and the acid liquid with the silver nitrate gives a mixed precipitate of silver metaborate and oxide. A. Basaroff accordingly stated that the liquid is a mixture of metaboric, hydrofluoboric, and hydrofluoric acids.

R. Abegg, C. J. J. Fox, and W. Herz studied the reactions between boric acid and hydrofluoric acid, and between boric acid and potassium fluoride, but came to no definite conclusions. They measured the partition coeff. of boric acid between water and amyl alcohol, and between a soln. of potassium fluoride and amyl alcohol; the f.p. of soln of boric acid and hydrofluoric acid and potassium fluoride; the electrical conductivity of mixtures of soln. of boric and hydrofluoric acids; and they made some titration experiments on the mixed acids. The conductivity of conc. hydrofluoric acid increased by the addition of boric acid, but with dil. soln. the conductivity is diminished. This means that boric acid combines with several mols of hydrofluoric acid, to form a complex acid which is highly ionized in conc. soln. The measurements are not independent of time, showing that the instantaneous reaction between the two acids, or between soln. of boric acid and potassium fluoride, is followed by another slower change.

J. Thomsen measured the heat, Q Cals., evolved on mixing boric acid, $B_2O_3aq.$, with n mols of hydrofluoric acid, and found for $(B_2O_3aq\ nHFaq.) = Q$ Cals.

nHF . . .	2	4	6	8	12
Q . . .	9·132	18·600	27·468	29·479	29·136

which shows that some kind of exothermal reaction occurs between the hydrofluoboric acid and the excess of hydrofluoric acid. O. Mulert represented the thermal changes which occur on mixing boric oxide or boric acid with hydrofluoric acid by Fig. 31. There is a preliminary period *ab* where very little change occurs; the temp. then suddenly rises, *bc*, and instead of remaining constant, *cd'*, the temp. continues to rise *cd*. The **heat of solution** of a mol of glassy boric acid in 3·65 per cent. hydrofluoric acid is given as 29·64 Cals.

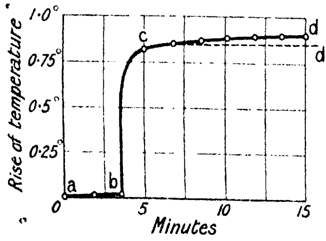

FIG. 31.—Thermal Changes on mixing Boric Oxide or Boric Acid with Hydrofluoric Acid.

In addition to J. J. Berzelius' acid, $H_2B_2O_4.6HF$, another acid, $HBO_3.3HF$, or $H_4BF_3O_2$, is said to be formed by the action of boron trifluoride on alcohol. Its sp. gr. was stated to be 1·1574, and its b.p. 92° at 3 cms. press. V. Gasselin said that the alleged acid is a mixture of the products of the hydrolysis of boron trifluoride, $2BF_3+3H_2O=2HF+HBF_4+H_3BO_3$. F. H. Landolph also reported $H_4B_2O_7.3HF$ to be formed as a clear yellow liquid, b.p. 160°, when boron trifluoride acts on amylene. The acid is said to fume in air, and to be decomposed by water. These results have not been confirmed.

J. J. Berzelius prepared crystals of what he regarded as **sodium boratofluoride,** $(NaO)_3.BF.2NaF.4H_2O$, or $F.B:(ONa)_2.2NaF.4H_2O$, by evaporating a soln. of a mol of sodium metaborate and 3 mols of sodium fluoride in boiling water. A. Basaroff stated that the product is really a mixture not a chemical individual—*vide supra*. J. J. Berzelius also reported two other sodium boratofluorides, one, $Na_2O.2B_2O_3.12NaF.22H_2O$, obtained from a mol of borax and 6 mols of sodium fluoride; and the other, (NaO)(HO)BF.2NaF, obtained from a cooling soln. of a mol of boric acid and 3 mols of sodium fluoride in boiling water. J. J. Berzelius also made **potassium boratofluoride** in a similar manner to that which he employed in making the sodium salts. A. Basaroff believed these products to be only mixtures. H. Schiff prepared two potassium boratofluorides whose composition can be represented by $B_2(OK)_2OF_2$, and $B(OK)_2F$; or

$$\begin{matrix}F\\OK\end{matrix}\!>B.O.B<\!\begin{matrix}F\\OK\end{matrix}$$

$$F-B<\!\begin{matrix}OK\\OK\end{matrix}$$

The former was made by fusing 7 parts of boron trioxide with 12 parts of potassium chloride, and extracting the matter soluble in alcohol from the cold cake; the latter was made by fusing the former in the calculated quantity of potassium carbonate. Both compounds dissolve in a small portion of water without decomposition, but with more water they are decomposed. J. J. Berzelius made **ammonium boratofluoride,** $2NH_4F.B_2O_3.6HF$, *i.e.* $2NH_4BF_4.3H_2O$, by heating a mol of boric oxide with eight mols of ammonium fluoride: $B_2O_3+8NH_4F=2NH_4F.B_2O_3.6HF+6NH_3$. G. I. Petrenko also made an ammonium boratofluoride, $(NH_4)HB_2F_2O_3$, or $(NH_4O)FB.O.BF(OH)$, by the action of hydrogen peroxide on a mixture of ammonium metaborate and fluoperborate. F. H. Landolph prepared what he regarded as **ethylene oxyfluoborate,** $C_2H_4.HFBO_2$, by the action of boric fluoride on ethylene in sunlight at 25°–30°. The clear mobile fuming liquid has a sp. gr. 1·0478 at 23°; b.p. 124°–125°; burns with a green flame; and is decomposed by water, forming boric acid and a volatile boron compound, b.p. 10°–15°, supposed to be an ethyl fluoride.

The liquid prepared by dissolving boron trifluoride in water until the soln. has an acid reaction is said to contain **hydrofluoboric acid,** HBF_4, which furnishes a series of well-defined salts, the **fluoborates,** also called *borofluorides*. M. Berthelot estimated the heat of formation of hydrofluoboric acid, HBF_4, to be (B, 4F, H)aq. =307·6 Cals. The ions of hydrofluoboric acid are $H^{\cdot}$ and BF_4'; a little of the latter possibly dissociates $BF'_4 \rightleftharpoons BF_3+F'$; and the boron trifluoride is partly hydrolyzed to hydrofluoric and boric acids, $BF_3+3H_2O=B(OH)_3+3HF$. A dil. soln. of hydrofluoboric acid does not attack glass, but a conc. soln. does. The acid is poisonous. I. Homeyer said that a 0·1–0·5 per cent. soln. of the acid or of its salts retards fermentation. F. Stolba also noted the feeble antiseptic qualities of the ammonium salt, *q.v.*

F. H. Landolph claimed to have made a more complex acid **hydrohexafluoboric acid,** H_3BF_6, or $BF_3.3HF$, as a heavy transparent liquid during the action of boron trifluoride on anethol. The acid is said to be easily isolated, to distil at about 130°, without exhibiting a constant b.p.; and to have a vapour density 4·72 calculated 4·42. It rapidly decomposes when exposed to moist air, forming boric and hydrofluoric acids. This result has not been confirmed.

§ 20. The Fluoborates

It is generally stated that J. J. Berzelius[1] discovered hydrofluoboric acid and the fluoborates in 1824, but, as a matter of fact, J. L. Gay Lussac and L. J. Thénard prepared a series of compounds by the action of a soln. of boron trifluoride in water on *les diverses bases salifiables* ; and their term *le gaz fluoborique* for boron trifluoride was probably based on the recognition of this fact. They called the soln. of the gas in water *l'acid fluoborique*, and noted its solvent action on zinc. They added :

> Il est probable qu'il existe des fluoborates de barite, de strontiane, de chaux, de potasse, de soude, de magnésie, de glucine, d'alumine, d'yttria, de zircone et de silice, et des fluo-borates métalliques ; et que tous ces sels sont autant de sels triples. On parviendroit probablement à faire tous ces sels, en fondant ensemble des fluates et des borates de la même base : et il est aussi tres probable qu'en traitant les fluo-borates par de l'acide sulfurique concentré, on obtiendroit facilement de l'acide fluo-borique.

J. J. Berzelius prepared the salts of hydrofluoboric acid, HBF_4, by the action of boron trifluoride on the metal fluoride ; by dissolving the metal oxide, hydroxide or carbonate in a soln. of hydrofluoboric acid ; by the action of hydrofluoboric acid on metal fluorides ; by the joint action of a metal fluoride and hydrofluoric acid on boric acid ; and by the action of a metal hydrofluoride on boric acid. As pointed out by W. C. Zeise, the last process presents the curious phenomenon of a mixture of two acid liquids producing an alkaline soln. ; $H_3BO_3+2NaHF_2=NaBF_4+NaOH+2H_2O$. Gebrüder Siemens made the alkali fluoborates by mixing boric acid and the alkali chloride into a thin paste with water, and adding hydrofluoric acid. The fluoborates are usually crystalline ; readily soluble in water ; lose boron trifluoride and form fluorides when calcined ; and, when distilled with sulphuric acid, they yield gaseous boron trifluoride, liquid hydrofluoboric and hydrofluoric acids, and a residual metal sulphate. Most of our knowledge of the fluoborates is still in the state left by J. J. Berzelius' memoir : *Untersuchungen über die Flussspathsäure und deren merkwürdigsten Verbindungen.*

J. J. Berzelius made **lithium fluoborate,** possibly $LiF.BF_3$ or $LiBF_4$: by treating barium fluoborate with lithium sulphate, and crystallizing the clear liquid by slow evaporation at 40°. The prismatic crystals deliquesce in air ; and taste like the sodium salt. The aq. soln. furnishes rhombic crystals. He also found sodium fluoride unites with hydrofluoboric acid, and the soln., when slowly cooled, furnishes " transparent, rectangular, four-sided prisms, often shortened and approaching the cubical form," presumably **sodium fluoborate,** $NaBF_4$, since they contain no water of crystallization. F. Stolba also made this salt. S. Motylewsky found the drop-weight of the molten salt to be 119 when that of water is 100 mgrms. at 0°. According to J. J. Berzelius, sodium fluoborate has a bitter acid taste, and it reddens litmus. The salt is slowly decomposed by heat : $NaBF_4=NaF+BF_3$, and it fuses below a red heat. It is more soluble in water than sodium hydrofluoride, but is only sparingly soluble in alcohol. F. C. Mathers and co-workers use an alcoholic soln. of hydrofluoboric acid for precipitating sodium fluoborate in the presence of potassium and magnesium salts J. O. Perrine observed no ultra-violet fluorescence with this salt.

J. J. Berzelius made **potassium fluoborate,** KBF_4, as a gelatinous precipitate by mixing hydrofluoboric acid with a soln. of a potassium salt. When washed and dried, it forms a gritty white powder. He also made the salt by dissolving a mol each of potassium hydrocarbonate and boric acid in an excess of hydrofluoric acid, and evaporating the soln. for crystallization. C. Montemartini used a somewhat similar process but with potassium carbonate. F. Stolba heated boric acid with potassium silicofluoride, and added potassium carbonate to the mixture ; he also warmed a mixture of 156 grms. of powdered fluorspar, 62 grms. of boric acid, 420 c.c. of hydrofluoric acid, for 2–3 hrs. in a flask with a reflux condenser, then diluted the mixture with half its vol. of water, and mixed the filtrate with a warm sat. soln. of potassium chloride or nitrate. The crystalline precipitate was washed with water, pressed, and recrystallized from a hot soln. of ammonia.

According to J. J. Berzelius, the salt has a feeble somewhat bitter taste, and is not at all acid to litmus. It crystallizes from its aq. soln. in " small shining, anhydrous, six-sided prisms with dihedral summits." According to C. Montemartini, the salt is dimorphous for the gritty powder indicated above, contains minute octahedra and dodecahedra belonging to the cubic system, and the crystals obtained by evaporating an aq. soln. of the salt belong to the rhombic system, and have axial ratios $a:b:c=2{\cdot}7898:1:1{\cdot}2830$. According to F. Zambonini, and T. V. Barker, potassium fluoborate and perchlorate are isomorphous. The former found a slight miscibility of up to 0·4 per cent. of potassium permanganate with the fluoborate. F. Stolba gave 2·498–2·524 for the sp. gr. at 20°. S. Motylewsky found the drop-weight of the molten salt is 103 when that of water at 0° is 100 mgrms. According to J. J. Berzelius, the undried crystals decrepitate when heated and give off some water and hydrofluoboric acid; according to F. Stolba, the wet crystals colour Bunsen's flame green, green and violet, and finally violet. J. J. Berzelius found that the dry salt is decomposed by heat into boron trifluoride, potassium fluoride, etc., as indicated above; a high temp. is required for decomposition. When heated rapidly, the salt fuses just below a red-heat—say, 500°. J. J. Berzelius found 100 parts of cold water dissolve 1·42 parts of the salt, while F. Stolba said 100 parts of water at 20° dissolve 0·448 part of the salt, and at 100°, 6·27 parts. The aq. soln. is at first neutral to litmus, but on standing, or on dilution, or heating, it becomes acid without attacking glass; F. Stolba said that in aq. soln. the salt is decomposed into potassium fluoride, hydrofluoboric acid, and hydroxyfluoboric acid, and that these components re-form potassium fluoborate when the soln. is evaporated. According to J. J. Berzelius, the salt is not decomposed by aq. soln. of ammonia, or of sodium or potassium hydroxide, or carbonate, and it is no more soluble in these soln. than it is in water. H. Rose found the salt to be more soluble in a soln. of ammonium chloride than it is in water, and A. Stromeyer said that it is not soluble in a 20 per cent. soln. of potassium acetate. H. Rose said that the salt is not soluble in cold alcohol, but, added J. J. Berzelius, it is a little soluble in hot alcohol and crystals are deposited when the soln. cools. When fused with alkali carbonates, A. Stromeyer, and J. C. G. de Marignac found that the fluoborate is decomposed into alkali fluoride and borate; and F. Stolba based a volumetric process for the determination of soda on this reaction. J. J. Berzelius found that the salt is decomposed by sulphuric acid; and F. Stolba by hydrofluosilicic acid, and by a mixture of silicic and hydrochloric acids.

F. Godeffroy prepared **rubidium fluoborate,** $RbBF_4$, and **cæsium fluoborate,** $CsBF_4$, in a similar manner to the preceding salt. F. Zambonini made the rubidium salt by adding rubidium carbonate to a soln. of boric acid in 35 per cent. hydrofluoric acid. The gelatinous mass, when washed and dried, forms a crystalline powder. Good crystals are obtained by the slow evaporation of the mother liquid from the gelatinous mass. F. Zambonini found that the rubidium salt is isomorphous with the rhombic form of the potassium salt, and that it has the axial ratios $a:b:c=0{\cdot}8067:1:1{\cdot}2948$; the sp. gr. of the rubidium salt is 2·820. F. Godeffroy found that 100 c.c. of water at 20° and 100° dissolve respectively 0·55 and 1·0 parts of the rubidium salt, and 0·92 and 0·04 part of the cæsium salt.

J. J. Berzelius obtained **ammonium fluoborate,** NH_4BF_4, by evaporating a soln. of his preparation of the oxyfluoborate. The product is sublimed to free it from boric acid. F. Stolba obtained the salt by sublimation from a mixture of boric acid and ammonium fluosilicate, and also by adding aq. ammonia to a sat. soln. of boric acid in hydrofluoric acid until the solution is alkaline; the liquid was then boiled, filtered, and cooled. The product was purified by crystallization from its aq. soln. a number of times. The salt tastes like ammonium chloride. The sublimate is white and pulverulent, but that deposited on the hotter parts may be fused and transparent. The crystals obtained from the aq. soln., said J. J. Berzelius, form "small six-sided prisms with dihedral summits." F. Stolba gave 1·851 for the sp. gr. at 17·5°. According to F. Stolba, the salt volatilizes from a platinum dish without leaving a residue; and it colours Bunsen's flame green, but the soln. in aq. alcohol burns with flame which is not green. In 1808, J. L. Gay Lussac and L. J. Thénard before J. J. Berzelius prepared ammonium fluoborate, and noted that it could sublime. F. Stolba found that 100 parts of water at 16° and 100° dissolve respectively 25 and

95–98 parts of the salt. J. J. Berzelius said that the salt also dissolves freely in alcohol. The aq. soln. reddens litmus, and, added F. Stolba, the soln. is feebly acid when freshly prepared; and turmeric paper, dipped in the soln. and moistened with hydrochloric acid, gives a boron stain when dried. The aq. soln. does not attack glass, and behaves like the soln. of the potassium salt. The salt is not changed by recrystallization from aq. ammonia.

By mixing soln. of cupric sulphate and barium fluoborate, and evaporating the filtrate, J. J. Berzelius obtained pale blue deliquescent needles, presumably of **cupric fluoborate,** $Cu(BF_4)_2$. He also prepared **calcium fluoborate,** presumably $Ca(BF_4)_2.nH_2O$, as a gelatinous precipitate by dissolving calcium fluoride in hydrofluoboric acid; he also made it by spontaneously evaporating an acid soln. of calcium carbonate in the same acid. The salt tastes acid, and reddens litmus. Water, especially hot water, decomposes the salt, dissolving out an acidic salt, and leaving behind a basic salt containing an excess of calcium fluoride. J. J. Berzelius prepared **dihydrated barium fluoborate,** $Ba(BF_4)_2.2H_2O$, by adding barium carbonate to an aq. soln. of hydrofluoric acid so long as it is dissolved; if too much barium carbonate is added, barium fluoride is formed and boric acid set free. On evaporation, any excess of boric acid crystallizes out first, and from the syrupy soln., barium fluoborate separates in "long rectangular four-sided prisms and needles, often with step-like depressions." The salt tastes like other barium salts, but not acid, although it reddens litmus. The salt loses its water of crystallization at 40°, and effloresces on the surface. When heated the salt first loses hydrofluoboric acid, then boron trifluoride, and leaves barium fluoride as a residue. The salt deliquesces in a moist atm., and is readily soluble in water. Alcohol decomposes it into an acid salt which dissolves, and a pulverulent basic salt which remains undissolved.

J. J. Berzelius prepared **magnesium fluoborate,** $Mg(BF_4)_2$, in large prisms with a bitter taste, and readily soluble in water; and **zinc fluoborate,** $Zn(BF_4)_2$, by dissolving zinc in an aq. soln. of hydrofluoboric acid until no more hydrogen was evolved. The soln. on evaporation furnishes a syrupy liquid which solidifies to a white deliquescent mass. J. L. Gay Lussac and L. J. Thénard also dissolved zinc in hydrofluoboric acid 16 years earlier than J. J. Berzelius. The last-named prepared **hydrated aluminium fluoborate,** possibly, $Al(BF_4)_3.nH_2O$, or $AlF_3.3BF_3.nH_2O$, by the slow evaporation of a soln. of aluminium hydroxide in hydrofluoboric acid. The product is soluble only in acidulated water. When soln. of aluminium chloride and sodium fluoborate are mixed, a basic compound separates, and the liquid contains free acid which retains a portion of the precipitate in soln. The product fuses at a red heat giving off water, and hydrofluoboric acid, and leaving aluminium borate as a residue. In a similar manner, J. J. Berzelius also made what was regarded as **yttrium fluoborate,** which if Y be the symbol for the mixture then thought to be yttrium, could be symbolized $Y(BF_4)_3.nH_2O$; he said that the salt is soluble only in water containing an excess of acid, and the soln. on evaporation furnishes crystals of the salt. He also prepared **cobalt fluoborate,** $Co(BF_4)_2$, as a white powder; and **lead fluoborate,** $Pb(BF_4)_2$. The last-named salt is made by adding lead carbonate, in small portions at a time, to hydrofluoboric acid, until a precipitate is formed. When the soln. is evaporated to a syrup, and cooled, it deposits long needles, but if slowly evaporated, "four-sided prisms or tables" are obtained. The taste at first appears sweet and astringent, but this is followed by a sensation of sourness. F. Fischer and K. Thiele obtained the salt in acicular crystals, but could not free the salt from the mother liquid on account of its extreme tendency to deliquesce. It is hydrolyzed by water to a soluble acid salt, and an insoluble basic salt. J. J. Berzelius added that if the salt is boiled for a long time with water or alcohol, this compound is resolved into an acid salt which dissolves, and a basic salt which remains undissolved as a white powder. An easily fusible basic compound was also said to be formed by heating lead with lead oxide. A. Miolati and G. Rossi made **cobaltic hexamminofluoborate,** or *luteocobaltic fluoborate,* $[Co(NH_3)_6]F_3.3BF_3.HF$, by adding a soln. of luteocobaltic carbonate to a soln. of boric acid in hydrofluoric acid. It can be recrystallized from dil. hydrofluoric acid; and it is stable at 110°–120°.

A series of complex **fluoperborates** has been obtained by G. I. Petrenko,[2] and P. G. Melikoff and S. Lordkipanidzé by the action of hydrogen peroxide on fluoborates, but *fluoperboric acid* has not been prepared. P. G. Melikoff and S. Lordkipanidzé obtained **potassium fluoperborate,** $K_4B_4F_4O_{10}.H_2O$, by treating an aq. soln. of potassium fluoborate, $2KF.B_2O_3$, with a slightly alkaline soln. of hydrogen peroxide, separates on the addition of alcohol as a viscous mass which becomes crystalline on stirring; the substance is redissolved in water and the process repeated, the salt being finally obtained in rhombic prisms. The following constitution, $OK.BF.O.O.BF.O.OK : OK.O.BF.O.O.BF.O.OK,H_2O$, is assigned to the compound. The aq. soln. has an alkaline reaction and slowly evolves oxygen at the ordinary temp., this decomposition being accelerated by warming; the silver salt is produced as a yellow precipitate by adding silver nitrate to the soln.; it is unstable, and blackens owing to the separation of metallic silver, oxygen being simultaneously evolved. The dry potassium salt is moderately stable; dil. sulphuric acid liberates hydrogen peroxide, whilst the conc. acid evolves ozonized oxygen. This salt may also be obtained by the action of hydrogen peroxide on potassium oxyfluoborate, $BF(OK)_2$. P. G. Melikoff and co-worker also precipitated the fluoborate, $K_2B_2F_2O_6.H_2O$, or $O_2(BF.O.OK)_2.H_2O$, by adding alcohol to the hydrogen peroxide soln. G. I. Petrenko also prepared the same salt. P. G Melikoff and S. Lordkipanidzé, and G. I. Petrenko obtained **ammonium fluoperborate,** $(NH_4)_2B_2F_2O_6.3H_2O$, by adding hydrogen peroxide, ammonia, and alcohol to a soln. of boric acid and ammonium fluoride. The white crystalline powder is moderately stable. The aq. soln. decomposes slowly at ordinary temp., and rapidly on warming. Ammonium peroxide acts as a base towards perboric acid; and the two unite, forming a salt-like compound.

§ 21. Boron Trichloride

J. Davy[1] observed that boron burns in chlorine gas, but he did not investigate the products of the combustion; J. J. Berzelius showed that **boron trichloride,** BCl_3, is formed when amorphous boron is warmed in chlorine gas. Dry amorphous boron ignites spontaneously in the gas, but boron which has been preheated has a higher temp. of ignition. H. Moissan gave 410° for the temp. of ignition. J. J. Berzelius' analyses were confirmed by G. Oddo and M. Tealdi, and by F. Wöhler and H. St. C. Deville. The last-named investigators first liquefied the gas. L. Gattermann recommended heating amorphous boron to dull redness in a stream of dried *hydrogen in order to get rid of moisture; the hydrogen is then replaced by chlorine. The temp. should be so regulated that the glass is attacked as little as possible.* The condensing apparatus must be well cooled with a freezing mixture since boron trichloride boils at a comparatively low temp., 13°. A. Stock and O. Priess condensed the crude chloride at −80°. It is shaken with mercury, or powdered silver to remove free chlorine; and it is redistilled in a fractionating column to get rid of hydrogen chloride and silicon chloride. The latter is produced by the joint action of boron and chlorine on the glass. A. Stock and O. Priess recommended distillation in a high vacuum from a bath at 78°. The early fractions, condensed by liquid air, contained hydrogen chloride, which influenced the vap. press. at 0° far more than the m.p., whilst the silicon chloride collected in the end fractions. A. Stock and E. Kuss discussed the purification of boron trichloride for at. wt. determinations. Modifications of this process have been described by F. Wöhler and H. St. C. Deville, H. Schnitlzer, E. Podszus, H. Gautier, C. M. Despretz, and H. C. C. Maisch. Boron trichloride was made by F. Wöhler and H. St. C. Deville by the action of hydrogen chloride on boron, but a high temp. is required and much silicon chloride is formed. They also made boron trichloride by heating boron with silver, mercury or lead chloride. P. C. Chabrié made boron trichloride by the action of carbon tetrachloride on boron at 200°–250°; $3CCl_4+4B=4BCl_3+3C$. C. Mazzetti and F. de Carli obtained almost quantitative yields by passing dry chlorine through a porcelain tube containing ferro-boron at 500°—*vide* silicon tetrachloride.

J. B. A. Dumas made boron trichloride by the action of chlorine on an intimate mixture of carbon and boric oxide at a high temp.: $B_2O_3+3Cl_2+3C=3CO+2BCl_3$. G. Gustavson obtained boron trichloride by heating in a sealed tube a mixture of boric oxide with an excess of phosphorus pentachloride for 3–4 days at 150°: $6PCl_5+5B_2O_3=10BCl_3+3P_2O_5$; no phosphoryl chloride is formed: he also found that if phosphorus trichlorodibromide be employed in place of phosphorus pentachloride, boron trichloride and free bromine are formed—virtually no boron tribromide is produced. H. Moissan found that boron trichloride is produced when boron sulphide, B_2S_3, is treated with chlorine, or with hydrogen chloride at 400°. H. Moissan and P. Williams obtained boron trichloride by treating calcium boride with chlorine. J. Tarible noted the formation of boron trichloride when arsenic trichloride acts on boron tribromide; and C. Councler, when boron oxytrichloride is heated: $3BOCl_3=B_2O_3+3Cl_2+BCl_3$. Boron chloro-hydrides have been described in connection with boron hydride.

Boron trichloride is a colourless gas which can be condensed to a colourless mobile liquid. Both gas and liquid form dense clouds in air. F. Wöhler and H. St. C. Deville gave 1·35 for the **specific gravity** of the liquid at 17·5°; A. Ghira gave 1·43386 at 0°/4°, and the latter gave 81·94 for the mol. vol. F. Wöbler gave 17° for the **boiling point** of the liquid; H. V. Regnault gave 18·23° at 760 mm.; P. Walden, 18·2°–18·8° at 767 mm.; and A. Stock and O. Priess, 13° at 764 mm. The last value is probably the best representative one. A. Stock and O. Priess' value for the **vapour density** of the gas is 58·43 ($H_2=2$); and F. Wöhler and H. St. C. Deville's value 3·97–4·065. The **vapour pressure** of the liquid was measured by H. V. Regnault, T. Tate, and A. Stock and O. Priess. The last-named gave for the vap. press., p, in mm. of mercury:

	−80°	−60°	−40°	−20°	−10°	0°	5°	10°	12·4°
p	4	18	67	197	314	477	579	695	753

The extrapolated value for the b.p. at 760 mm. is 12·5°. H. V. Regnault gave for p mm.,

	−20°	−10°	0°	10°	20°	30°	40°	60°	80°
p	159·46	250·54	381·32	562·94	807·50	1127·50	1535·25	2658·52	4248·28

H. V. Regnault represented his measurements at $\theta°$ by the formula $\log p = 4·8159298 - 2·7690345a^t + 0·0120096b^t$, when $\log a = \bar{1}·9965575$, and $\log b = \bar{1}·9770709$, and $t = \theta + 27$; below 0° the last term may be omitted. C. Antoine epresented the vap. press. of boron trichloride by log $p=0{\cdot}9290(7{\cdot}1268-1000/t)$, where $t=\theta^\circ+130^\circ$. A. Stock and O. Priess gave −107° for the **melting point**. The **heat of formation** from amorphous boron, as given by M. Berthelot, is 89·1 Cals. for the gas, and 93·4 for the liquid. This makes the mol. **heat of vaporization** 4·3 Cals. L. Troost and P. Hautefeuille gave 104 Cals. for the heat of formation of the gas, and for the **heat of solution** of the gas in 100 times its weight of water, 7·2 Cals. per gram, or 79·2 Cals. per eq. According to P. Walden, the **electrical conductivity** of the liquid is virtually nil, and it shows no tendency to ionize binary salts and strong acids at 0°.

By subjecting a mixture of boron trichloride and **hydrogen** at ordinary temp. to the silent electric discharge, H. V. A. Briscoe found that a pale yellow transparent substance is produced with a smaller atomic ratio than B : Cl=1 : 3—possibly *boron subchloride*. It is rapidly decomposed by water with the evolution of hydrogen and the formation of a soln. with reducing properties. According to C. A. A. Michaelis and P. Becker, if a mixture of boron trichloride and **oxygen** is exposed to the silent electric discharge in an ozone tube, very little boric oxide is formed, but if the mixture be sparked, a vigorous action occurs: $4BCl_3+3O_2=2B_2O_3+6Cl_2$; **ozone** does not attack the gas. C. A. A. Michaelis and P. Becker did not detect any signs of the formation of an oxychloride in their study of the action of oxygen and of ozone on boron trichloride. Gaseous and liquid boron trichloride react with **water,** forming hydrochloric and boric acids. The reaction has been studied by F. Wöhler and H. St. C. Deville, and J. von Liebig. J. B. A. Dumas said that if a small proportion of water be used a solid hydrate is formed, and this, when heated in a stream of hydrogen, furnishes hydrochloric and boric acids. According to H. Moissan, when **fluorine** is passed into boron trichloride, each bubble of fluorine forms boron trifluoride. Boron trichloride reacts with **hydrogen iodide** at a high temp., forming boron iodide. A. Stock and O. Priess say that **chlorine** has no perceptible action on boron trichloride even at −80°. G. Gustavson said that **sulphur** does not act on the gas at 250°. According to A. Stock and O. Poppenberg, **hydrogen sulphide** forms boron sulphide at a red heat. G. Gustavson found that when a mixture of boron trichloride with **sulphur trioxide** is heated in a sealed tube at 150°, a reaction, probably $2BCl_3+3SO_3=3SO_2Cl_2+B_2O_3$ occurs. H. Moissan found that **sulphur tetrachloride,** SCl_4, gives a liquid double chloride, which freezes at −33°.

W. Jevons found that with the so-called active form of **nitrogen,** boron trichloride forms a white amorphous solid containing both nitrogen and boron, the reaction is accompanied by a pale bluish-green glow quite different from the green colour of the flame tinted with boric acid. According to J. J. Berzelius, one vol. of boron trichloride unites with 1½ vol. of **ammonia** producing a white substance, **boron sesquiamminochloride,** $2BCl_3.3NH_3$. C. A. Martius prepared this compound by passing dry ammonia into cooled liquid boron trichloride. The compound does not fume in air; it is rather less volatile than ammonium chloride, and sublimes undecomposed. It is decomposed by water, forming hydrochloric acid, and ammonium chloride and borate. When mixed with ammonia, and passed through a hot tube, it forms spontaneously inflammable boron nitride. A. Besson stated that ammonia displaces the hydrogen phosphide from boron phosphinochloride at 8°, and yields **boron hemienneamminochloride,** $2BCl_3.9NH_3$, which alters but slowly when exposed to air, and does not lose ammonia below 50°, but is immediately decomposed by water with the production of a slightly alkaline soln. According to A. Joannis, the variable results obtained by the action of ammonia on boron trichloride are due to the complexity of the reaction; additive compounds are not formed, but rather mixtures of ammonium chloride. Thus, with **boron hexamminochloride,** $BCl_3.6NH_3=B(NH_2)_3+3NH_4Cl$; and $2B(NH_2)_3=B_2(NH)_3+3NH_3$. The ammonium chloride can be washed out with liquid ammonia—*vide* silicon hexammino-tetrachloride and zirconium octammino-tetraiodide. A. Joannis added that when a current of hydrogen carrying the vapour of boron chloride is passed through *liquid ammonia at −70° to −50°, and the temp. raised to volatilize the excess of ammonia, a mol of boron chloride fixes 15 mols of ammonia, and when the temp. is raised to 0°, 9 mols of ammonia are expelled, and the vap. press. is the same as that* of $NH_4Cl.3NH_3$. During this reaction no nitrogen or hydrogen is evolved, and from the increase in weight, and the action of water, whereby boric acid is formed, it is inferred that three amido-groups united to boron are produced from the three ammonia groups, so that the reaction at −23° is $BCl_3+15NH_3=B(NH_2)_3+3(NH_4Cl.3NH_3)$; and at 0°, $BCl_3+6NH_3=3NH_4Cl+B(NH_2)_3$. The *boramide*, $B(NH_2)_3$, cannot be separated completely from the ammonium chloride, although the latter is more soluble in liquid ammonia. When the boramide is heated to 440°, it loses 1·5 mols of ammonia and is slowly converted into **borimide,** $B_2(NH)_3$, by a reaction: $2B(NH_2)_3=3NH_3+B_2(NH)_3$. This reaction begins at ordinary temp. Borimide can be readily separated from ammonium chloride by washing out the latter with liquid ammonia. A. Stock and M. Blix prepared white pulverulent **borimide trihydrochloride,** $B_2(NH)_3.3HCl$, by allowing borimide to react with hydrogen chloride. It is decomposed by water, and is insoluble in the usual organic solvents.

Boron trichloride has a marked tendency to form complexes. According to A. Geuther, when boron trichloride is treated with **nitrogen tetroxide** an energetic action takes place, a solid substance being deposited in the liquid, while yellow crystals condense on the sides of the flask. When distilled after standing two days, volatile yellow crystals condense in the receiver, and the brownish-red vapour of these crystals fume on coming in contact with the air. A liquid which appears to be a soln. of the crystals in boron trichloride also passes over. The crystals have a composition corresponding with **boron nitrosylchloride,** $BCl_3.NOCl$. The reaction is probably $16BCl_3+6N_2O_4=2B_2O_3+12(BCl_3.NOCl)+3O_2$. The compound forms rhombic octahedrons or prisms which dissolve in water with a hissing sound, boric acid, nitric acid, and chlorine being produced. At 23°–24° the crystals melt, forming two layers of fluid, the upper of which appears to consist of boron trichloride containing a small portion of the original substance, while the lower probably consists of the fused substance together with a small portion of nitrosyl chloride. On cooling, the two layers reunite with more or less rapidity, according to circumstances, reproducing the original substance.

A. Besson found that phosphine combines with boron chloride with development of heat, and yields white **boron phosphinochloride,** $BCl_3.PH_3$, which alters rapidly when exposed to air, and is immediately decomposed by water with liberation of hydrogen phosphide. It begins to dissociate at 20° under the ordinary press., and if the products of dissociation be slowly cooled, the compound is obtained in bulky, colourless, highly refractive crystals. G. Gustavson said that when boron trichloride is heated with **phosphorus pentoxide** in a sealed tube, a crystalline complex, **boron phosphoryl chloride,** $POCl_3.BCl_3$, is formed; $P_2O_5+2BCl_3=PBO_4+POCl_3.BCl_3$; and that with **phosphoryl chloride** a similar product is obtained, but G. Oddo and M. Tealdi denied the formation of a crystalline compound under these conditions.

H. Schiff noted that boron trichloride reacts with **alcohol,** forming ethyl borate, and C. Councler studied its action on different alcohols. G. Gustavson said that boron trichloride readily reacts with organic compounds containing OH- or NH_2-groups. S. Rideal studied its action on **aniline**; C. A. Martius, with **hydrogen cyanide,** and with **cyanogen chloride**; G. Gustavson, with **carbon tetrabromide**; and with **potassium cyanide**; A. Gautier, with **ethyl cyanide.** E. Frankland found boron trichloride converts **zinc ethyl** into **boron ethyl,** $B(C_2H_5)_3$. C. A. A. Michaelis and P. Becker, F. J. Schumacher, W. Dilthey, and A. Rosenheim and co-workers made boro-organic compounds. Boron trichloride reacts so energetically with **fat** that A. Stock and O. Priess devised a special valve to avoid the use of greased taps.

A and *B*, Fig. 32, are solid glass floats, resting by three feet on the enlargement in the tubes, and ground at the top to fit into the ground constriction. *C* and *D* connect the other pieces of apparatus. The bulb *E* contains clean mercury. When *A* and *B* have fallen, *C* communicates with *D*. By raising the mercury in *F*, the floats are forced into constrictions, to make, with a thin film of mercury, a gas-tight seal. The floats are made to fall again by evacuating *E* and opening the tap *G*.

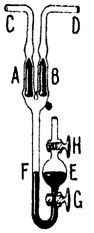

Fig. 32. Valve to replace the Greased Tap.

According to G. Gustavson, boron trichloride can be distilled from **sodium** without alteration, but at 150°, some boron is formed; A. C. Vournasos found the boron halides are reduced with difficulty by **potassium.** **Sodium amalgam** is covered with a film of boron after being in contact with boron trifluoride for a day; **zinc** dust does not react at 200°, but **magnesium** was found by F. Jones and R. L. Taylor to furnish magnesium boride: $6Mg+2BCl_3=3MgCl_2+Mg_3B_2$, and **iron** reduced in hydrogen was also found by H. Moissan to form iron boride. N. Parravano and C. Mazzetti found both **nickel** and iron form borides when heated in an atm. of boron trichloride. A. Stock and O. Priess said that boron trichloride does not attack hot **mercury.** L. Troost and P. Hautefeuille found that boron trichloride reacts with **silica** at a high temp., forming boric oxide and silicon tetrachloride; and that **titanic oxide,** TiO_2, and **zirconia,** ZrO_2, act in an analogous manner. They also found that with **alumina,** aluminium chloride and aluminium borate are formed; and that **porcelain** is attacked at a bright red heat, forming aluminium and silicon chlorides, aluminium borate, etc. G. Gustavson stated that when eq. quantities of boron trichloride and **boric oxide** are heated in a sealed tube at 150°, **boron oxymonochloride,** $BOCl$, is formed, but R. Lorenz tried to confirm this and found that the product is a mixture of boron chloride and oxide, $2BCl_3+7B_2O_3$. C. Councler claimed to have obtained **boron oxytrichloride,** $BOCl_3$, as a by-product in the preparation of boron trichloride; he described it as a yellowish-green liquid which decomposes on heating into boron trichloride, chlorine, and boric oxide; and with water it forms chlorine, and boric and hydrochloric acids. In R. Lorenz's attempt to make this compound by passing chlorine over a mixture of boric oxide and charcoal, he obtained a liquid mixture of boron trichloride and benzene hexachloride. The oxychloride remains as a white fibrous mass when the liquid is distilled; it had a composition $B_8O_{11}Cl_2$, or $11B_2O_3+2BCl_3=3B_8O_{11}Cl_2$; and not $BOCl_3$ as stated by C. Councler.

§ 22. Boron Tribromide

A. B. Poggiale[1] first obtained **boron tribromide,** BBr_3, by the action of bromine vapour on an intimate mixture of carbon and boric oxide at a red heat. He did not condense his product to a liquid. F. Wöhler and H. St. C. Deville made the tribromide by passing bromine over boron at a dull red heat. Before passing the bromine, the apparatus is dried by passing a stream of dried hydrogen over the heated boron. H. Gautier, J. L. H. Abrahall, H. Moissan, A. von Bartal, and A. Stock and E. Kuss employed a similar process. The crude boron tribromide condenses in a well-cooled receiver as a yellow liquid. The product is purified by shaking it with mercury, and it is rectified at atm. press. by fractionation with a distillation column. A. Stock and E. Kuss also discussed the purification of the bromide for at. wt. determinations. F. Meyer and R. Zappner purified the bromide by distillation under reduced press. P. C. Chabrié noted that a little boron bromide is formed when a mixture of amorphous boron with ethylene dibromide, or tribromohydrine, is heated in a sealed tube. H. Moissan noted the formation of boron tribromide when boron sulphide is heated with bromine; and G. Gustavson, when a mixture of boric oxide and phosphorus pentabromide is heated in a sealed tube at 140°. A. Stock and E. Kuss described the preparation of the tribromide of a high degree of purity. The boron bromo-hydrides have been described in connection with the boron hydrides.

Boron tribromide is a colourless fuming liquid. F. Wöhler and H. St. C. Deville gave 2·69 for the sp. gr., and A. Ghira gave 2·94985 at 0°/4°, and T. Ewan and P. J. Hartog gave 2·6175 at 16·5°; and for the mol. vol., A. Ghira gave 94·72 at 0°. F. Wöhler and H. St. C. Deville found the vap. density to be 8·78, the normal value is 8·772 (air unity); A. B. Poggiale found 8·46. F. Wöhler and H. St. C. Deville, and H. Gautier found the b.p. to be 90·5°; A. von Bartal, 90·6°; and A. Stock and E. Kuss, 90·1° at 740 mm. The last-named found the mol. wt., from the f.p. of benzene soln., to be 252; and the vap. press., p in mm. of mercury to be:

	50	−30°	−10°	0°	10°	30°	50°	70°	90°
p . . .	0·7	3	10·5	19	32	85	193	300	730

They also gave −46° for the m.p. of boron tribromide; H. Gautier gave −44°. M. Berthelot gave for the heat of formation $(B, 3Br_{gas})=543$ Cals. and $(B, 3Br_{liquid})=43·2$ Cals. for liquid boron tribromide.

H. Gautier said that **water** reacts with boron tribromide with explosive violence. F. Wöhler and H. St. C. Deville merely mentioned the existence of boron oxybromide; A. Besson, that **hydrogen iodide** replaces one or two atoms of bromine by iodine; A. Stock and O. Poppenberg found that **hydrogen sulphide** converts it into boron sulphide; and G. Gustavson, that with **sulphur trioxide** in a sealed tube at 120°, the compound $B_2O_3.SO_3$ is formed. According to A. Besson, ammonia gas combines directly with boron bromide with great development of heat and partial conversion into boron nitride. In order to obtain a definite compound, rise of temp. must be avoided. If dry ammonia, cooled to 0°, be passed into a soln. of boron bromide in dry carbon tetrachloride, cooled to 0°, a white, solid substance separates, and at the end of the reaction the solvent is expelled by means of a current of dry air at 50°–60°. The product is amorphous, and corresponds with **boron tetrammino-tribromide,** $BBr_3.4NH_3$. At 10° it absorbs more ammonia, but the excess is expelled in a current of dry air. When heated in dry oxygen, decomposition begins at about 150°, without sublimation, the products being boron nitride and ammonium bromide.

The compound is also decomposed by water and alkalies. A. Stock treated boron arsinotribromide, $BBr_3.AsH_3$, with ammonia at −25°, and obtained a liquid which gives off the excess of ammonia when warmed and forms a white solid corresponding with **boron enneamminotribromide,** $BBr_3.9NH_3$. A. Joannis considered that the products of the action of ammonia on boron tribromide are ammonium bromide and boramide—*vide* boron trichloride. A. Stock noted that with **phosphine,** $BBr_3.PH_3$, is formed; with **phosphorus trichloride,** $2BBr_3.PCl_3$; with **phosphorus pentachloride,** $2BBr_3.PCl_5$; with **phosphoryl chloride,** $BBr_3.POCl_3$; with **phosphorus tribromide,** $BBr_3.PBr_3$; with **phosphorus pentabromide,** $BBr_3.PBr_5$; with **phosphorus iodides,** $2BBr_3.P_2I_4$; and with **arsine,** $BBr_3.AsH_3$ is formed. J. Tarible found that **arsenic trichloride** reacts; $AsCl_3+BBr_3=AsBr_3+BCl_3$; **antimony trichloride** reacts in an analogous manner; while **arsenic tribromide, arsenic tri- and penta-iodides, antimony tribromide,** and **antimony tri-iodide** are readily dissolved by boron tribromide. G. Gustavson found that when a mixture of boron tribromide and **carbon tetrachloride** is heated in a sealed tube at 150°–200°, about 10 per cent. of the boron forms the trichloride; and A. Besson found that **carbonyl chloride** is converted into the chlorobromide and bromide under similar conditions. S. Rideal, C. A. A. Michaelis, etc., have studied the action of boron bromide on **organic compounds.**

§ 23. Boron Triiodide

J. Inglis[1] obtained a small quantity of a yellow sublimate by passing iodine vapour over an intimate mixture of carbon and boric oxide at a red heat; the product was thought to be an impure boron iodide; but F. Wöhler and H. St. C. Deville were not able to make boron iodide by the direct union of the elements nor by heating a mixture of boron with silver iodide. H. Moissan first established the existence of **boron triiodide,** BI_3, which he obtained in 1891 by heating a mixture of the vapours of boron trichloride and hydrogen iodide; by the action of iodine vapour on the amorphous boron of F. Wöhler and H. St. C. Deville, at 700°–800°; and by the action of hydrogen iodide on red-hot amorphous boron. The last-named process is considered to be the best. The boron is first heated to about 200° in a stream of dried hydrogen. It is then heated in a Bohemian glass tube, almost to the m.p. of the glass. A stream of hydrogen iodide, dried by passage over calcium iodide, is passed through the tube. The boron triiodide sublimes in large lamellæ which have a purple-red colour owing to the presence of a little free iodine; the crude product is purified by dissolving it in carbon disulphide, shaking it with mercury to remove free iodine, and recovering the iodide by evaporating the soln. It is considered remarkable that the amorphous boron of H. Moissan is not satisfactory, while the less pure preparation by F. Wöhler and H. St. C. Deville's process is satisfactory. A. Besson said that only a small portion of the boron is attacked, and that this portion must be a more active variety than the remainder of the boron, but H. Moissan said that the more active variety is probably a mixture of iron and sodium borides. A. Besson also obtained a mixture of boron dibromoiodide, and bromodiiodide, with boron triiodide, by passing a mixture of the vapours of hydrogen iodide and boron tribromide through a glass tube heated to 300°–400°. After shaking the mercury, the three constituents can be separated by repeated fractional distillation, **boron dibromoiodide,** BBr_2I, boils at 125°; **boron bromodiiodide,** $BBrI_2$, at 180°; and boron triiodide at 210°. The yields are poor. The two bromoiodides are colourless liquids. Light alone has no action on them, but moist air and light decompose both compounds as in the case of boron triiodide. Both compounds are decomposed by water with violence.

Boron triiodide forms colourless crystals. According to H. Moissan, the compound melts at 43°, and readily crystallizes on cooling; the sp. gr. at 50° approximates to 3·3; the liquid boils undecomposed at 210°. Boron triiodide is not changed by an electric current of 50 volts. The crystals are very hygroscopic, and readily decompose on exposure to air, or to light, and iodine is liberated. A. Besson said that light alone does not appear to have any action, and he thinks that the moisture first decomposes the iodide into boric and hydriodic acids, and that the latter is decomposed by air and **light** into iodine and water. H. Moissan found that boron triiodide is not altered when heated to redness in a stream of **hydrogen.** When the vapour is heated to redness in a glass tube, it burns when brought in contact with the **air,** and iodine is then set free; a similar result is obtained by heating the iodide in **oxygen.** Boron triiodide is immediately decomposed by **water** into a mixture of boric and hydriodic acids without the separation of iodine. It is rapidly attacked by melted sulphur; at 400°, boron trisulphide is formed; a soln. of **sulphur** and boron triiodide in carbon disulphide at ordinary temp. forms boron pentasulphide.

According to A. Besson, **ammonia** unites with boron triiodide with the development of much heat. When a current of ammonia cooled to 0° is passed into a soln. of boron triiodide in carbon tetrachloride, cooled to 0°, white amorphous **boron pentamminotriiodide,** $BI_3.5NH_3$, separates. This becomes brown when exposed to light; a little iodide is also decomposed when the salt is heated in a current of hydrogen, iodine being liberated; and it is decomposed by water. In a current of dry ammonia, the pentammine absorbs the gas rapidly, and yields a liquid approximately of the composition of **boron pentadecamminotriiodide,** $BI_3.15NH_3$; but even at 0° this compound is unstable, and in a current of dry air it gradually loses ammonia, and is reconverted into the original compound. According to A. Joannis, it is probable that additive compounds are not formed by the action of ammonia on boron triiodide, but rather a mixture of ammonium iodide and boramide—*vide* boron chloride. Boron triiodide reacts with warm **phosphorus** (ordinary or red) with incandescence; but H. Moissan found that with soln. of the two substances in carbon disulphide, in a closed vessel, **boron phosphoiodide,** BPI_2, is formed; he also found that boron triiodide dissolves in liquid **phosphorus trichloride** or in liquid **arsenic trichloride.** A. Besson said that boron triiodide forms a crystalline compound with **phosphine.** H. Moissan found boron triiodide reacts vigorously with **phosphoryl chloride.** Boron triiodide is readily soluble in **carbon disulphide,** in **carbon tetrachloride,** and in **benzene.** Absolute **alcohol** reacts thus: $6C_2H_5OH+2BI_3=2H_3BO_3+6C_2H_5I$; **ether** reacts: $3(C_2H_5)_2O+BI_3=3C_2H_5I+B(OC_2H_5)_3$. Most ethers, carbohydrates, and ammonium-bases react vigorously with boron triiodide.

According to H. Moissan, boron triiodide can be distilled unchanged from **sodium,** but at a red heat there is a reaction; **magnesium** acts at 500° with incandescence; **silicon** is not attacked at a dull red heat; **aluminium,** and **silver** do not react with boron triiodide at 500°; but **silver fluoride** reacts in the cold, forming silver iodide and boron trifluoride.

§ 24. Boratochlorides, Boratobromides, and Boratoiodides

The mineral **boracite** is comparatively rare ; it was described by G. S. O. Lasius[1] in 1787 as a *cubical quartz ;* in 1788, J. F. Westrumb found that it contained boric acid, magnesium, and calcium, and hence called it *Lüneberg sedative spar ;* A. G. Werner named it *borazite*. L. N. Vauquelin called it *borate magnésio-calcaire*. An analysis by C. H. Pfaff in 1813 corresponded with the formula MgB_2O_4, but it was not until 1858 that H. Rose, and W. Heintz demonstrated that magnesium chloride is an essential and not an accidental constituent. It occurs in crystals embedded in anhydrite, gypsum, or rock salt, at Kalkberg and Schildberg (Luneberg, Hanover) ; Seegeberg (Kiel, Holstein) ; Douglashall (Westeregeln), Leopoldshall (Stassfurt), Solvayshall (Bernburg) ; Luneville (La Meurthe, France) ; and, as shown by M. R. Campbell, among the borates of Nevada and Oregon (United States). A massive variety was called *stassfurtite* by G. Rose ; it occurs in the carnallite and kainite zone of the Stassfurt salt deposits, and it may resemble fine-grained marble, or granular limestone, or it may be more or less earthy and tinted variously green, yellow, or red by impurities. The occurrence of stassfurtite has been studied by J. Nöggerath, E. Reichardt, F. Bischof, H. E. Boeke, C. J. B. Karsten, etc. Analyses of boracite crystals have been made by F. Stromeyer, J. A. Arfvedson, C. F. Rammelsberg, H. Rose, L. Potyka, W. Heintz, etc. ; and analyses of stassfurtite have been made by C. J. B. Karsten, W. Heintz, C. F. Chandler, H. Ludwig, L. Potyka, H. Precht and B. Wittjen, etc. The results are best represented by the formula : $Mg_7B_{16}O_{30}Cl_2$, or $6MgO.8B_2O_3.MgCl_2$, **magnesium hexadecaboratodichloride.** F. Bischof uses $(3MgO.4B_2O_3)_2MgCl_2$ for boracite, and $(3MgO.4BO_3)(3FeO.4B_2O_3)MgCl_2$ for iron boracite. P. Groth regards boracite as a salt of diboric acid in which the two chlorine atoms are united directly to boron, and not to magnesium, $Cl.B : O_2 : B.O.Mg(O.B : O_2 : B.OMg)_6O.B : O_2 : B.Cl$. The analyses range from 58·90 to 69·77 per cent. of boric oxide ; 24·93 to 33·0 per cent. of magnesia ; and 9·97 to 11·75 per cent. of magnesium chloride. The ferric oxide ranges up to 1·6 per cent., and a variety with about half the magnesia replaced by ferrous oxide was called *iron boracite*, or rather *Eisenstassfurtit*, by A. Huyssen. The water in the analyses of crystals of boracite ranges up to about 2 per cent., but in the massive stassfurtite up to 11·27 per cent. has been reported. C. F. Chandler said that stassfurtite retains no water if dried at 100°. The mineral is slightly deliquescent on exposure, and this led to the view discussed by F. Bischof, and A. Steinbeck that there is a hydrated boracite ; the plumose interior of some crystals of boracite was called *parasite*, by G. H. O. Volger, and is probably a result of this action. L. Potyka observed the conversion of boracite to stassfurtite by the slow absorpton of water.

Boracite was synthesized by L. Bourgeois, and W. Heintz by slowly cooling a molten mixture of magnesia and boric acid with a great excess of sodium and magnesium chlorides. The product is washed first with water and then with cold conc. hydrochloric acid until the prismatic crystals of magnesium borate have been removed. The product is washed and dried. A. de Gramont heated a mixture of one part of borax with two parts of magnesium chloride with a little water for 2 or 3 days in a tube at 275°–280°. G. Rousseau and H. Allaire obtained boracite by the action of the vapour of magnesium chloride on boronatrocalcite.

The crystals of boracite have attracted much attention. At first sight they appear to belong to the cubic system and to have polar ditesseral symmetry. The ordinary form is that of a cube with an octahedron and dodecahedron; but usually, the faces of one tetrahedron are large, and those of the other small; and one is bright, and the other dull. The crystals have been studied by B. Schultze, C. Klein, H. Bücking, H. Baumhauer, O. Mügge, F. Rinne, A. Karnojitzky, etc. C. Ochsenius observed pseudomorphs of boracite after quartz. The cubic form of boracite crystals naturally suggests that the crystals will be singly refracting and optically isotropic. On the contrary, boracite exhibits an anomalous double refraction, for it is strongly doubly refracting, and exhibits brilliant polarization colours. This is not characteristic of cubic crystals. D. Brewster first established the birefringency of boracite. Between crossed nicols, the mineral sometimes appears to have a fibrous or lamellar structure. A thin slice cut parallel to one of the cube faces shows a division into four fields along the diagonals of the face, and each field exhibits an optic axis characteristic of biaxial crystals; there are also twin laminations. J. B. Biot attributed the phenomenon to the separation of the crystal into a system of plates; F. C. Naumann, G. H. O. Volger, H. Marbach, F. Klocke, and F. E. von Reusch to the existence of strains produced when boracite originally crystallized at a high temp. as a cubic mineral, and developed stresses and strains during the contraction on cooling. P. Groth pointed out that boracite is found enclosed in gypsum, a hydrated mineral which could not be formed at a high temp. except under a great press. The internal strain hypothesis is not likely in view of the fact that each portion of the crystal has a definite refraction, birefringence, and axial angle, showing that the various portions differ only in their orientation. The crystal of boracite, indeed, consists of definite individuals united by twinning on planes parallel to the dodecahedron faces of the cubic crystal. E. Mallard's hypothesis is generally accepted:

> Imagine a rhombic dodecahedron to be constructed of twelve pyramids, each having a dodecahedron face for base, and its apex at the centre of the crystals. Each of these will then be one of the twelve rhombic or monoclinic individuals which form the crystal of boracite; the axial plane of each crystal will be parallel to the longer diagonal of the rhombic face, and a bisectrix perpendicular to the face; the true axial angle being about 90°, one optic axis will be perpendicular to each cube face. The interpenetrating constituent crystals meet in irregular boundaries.

E. Mallard showed that the rhombic constituents of the boracite crystals have the axial ratios $a:b:c=0.70715:1:1$. H. Baumhauer, O. B. Böggild, C. Klein, J. Beckenkamp and W. Agafonoff have also studied the twinning of boracite crystals. H. Baumhauer found the corrosion figures with a mixture of hydrochloric and sulphuric acids are in harmony with E. Mallard's hypothesis.

When a section of a crystal of boracite is heated, the birefringence of the different portions changes, as is demonstrated by the change in the interference tints; the boundaries move and often take up different positions when the section is allowed to cool. E. Mallard further showed that at 265°, all these optical differences abruptly disappear, and the crystal becomes isotropic, and is dark between crossed nicols; on cooling, the optical anomalies, complex structure, and twin lamination reappear. This shows that boracite is dimorphous, and that above 265° the crystal is isotropic and cubic; and below that temp. it is biaxial, probably rhombic. W. Schwarz gives 265·2° for the enantiotropic transition temp. F. Rinne found a greyish-green boracite with 7·9 per cent. of ferrous oxide, changed to a deep bluish-green when heated, but the green colour was restored on cooling. The transition temp. was raised 20° by the contained iron. According to R. Brauns, the doubly-refracting boracite found in salt deposits first crystallized in the cubic form below its transition temp., 265°. O. Mügge assumed that there must have been a local rise of temp. during crystallization, but R. Brauns believed that the metastable crystalline form usually separates first—*e.g.* sulphur, potassium nitrate, and mercuric iodide—and with boracite the metastable cubic form was first produced.

C. J. B. Karsten gave 2·75 for the sp. gr. of boracite; F. Bischof, 2·667; E. Reichardt, 2·38–2·458; C. F. Rammelsberg, 2·955; H. Ludwig, 2·507; C. F. Chandler, 2·994; and F. von Kobell, 2·91 before and after calcination. A. de Gramont gave 2·89 for the sp. gr. of the artificial crystals, and B. Schultze, 2·90–2·92. Boracite is harder than felspar; the hardness is 7 on Mohs' scale. W. Meyerhoffer found an increase in vol. with rise of temp. up to 255°, and from 265°–267° a decrease in vol. J. J. Berzelius found that boracite melts before the blowpipe, forming a clear glass which cools to an opaque glass with needle-like crystals; and G. Rose added that stassfurtite behaves similarly, but is rather more fusible. E. Mallard and H. le Chatelier observed a slow increase in the sp. ht. with rise of temp. up to 252°, and a rapid rise between 252° and 277°, and after that a small decrease. The mean sp. ht. of rhombic boracite, according to W. Schwarz, is 0·246, and of cubic boracite, 0·265. K. Kröker found the sp. ht. of hexahedral and of dodecahedral boracite to be.

	−32°	50°	100°	200°	270°	300
Hexahedral .	0·1607	0·2124	0·2398	0·2901	0·2650	0·3757
Dodecahedral .	—	0·2157	0·2398	0·2901	0·2532	0·4781

The results in the former case are represented by $0·1809614+0·0006313844\theta-0·000000428\,4\theta^2$; and in the latter case by $0·1809647+0·0006313844\theta-0·0000004284\theta^2$. D. Brewster found the index of refraction to be 1·701. E. Mallard gave for the mean index of refraction for white light, $\alpha=1·6622$; $\beta=1·6670$; and $\gamma=1·6730$. E. Marbach measured the effect of temp. and found for light $\lambda=5016$, 1·6776 at 290°, and 1·6796 at 502°; and for $\lambda=5876$, 1·6714 at 290° and 1·6741 at 502°. P. Gaubert measured the effect of press. on the double refraction of the crystals. R. J. Haüy found in 1791 that when a cube of boracite is heated, it becomes positively electrified on four of its corners, and negatively on the remaining four corners. Hence if a mixture of red-lead and sulphur be blown or sieved upon the crystal, four of the corners negatively electrified will be coloured by the red-lead as the crystal cools, and the other four corners will be coloured by the sulphur. The subject has been further studied by F. Köhler, W. Hankel, P. T. Ries and G. Rose, E. Marbach, C. Friedel and J. Curie, A. Kundt, and W. C. Röntgen. K. Mack showed that the pyroelectrical behaviour disappears at 265°, and is mainly developed along certain lines which traverse the surface of the crystal, and that these are the lines of contact of the twelve sub-individuals whose existence is indicated by the optical properties of the crystal. J. and P. Curie found that piezoelectrical properties are developed in crystals of boracite such that cooling and compression develop the same electrification at the same corners of the crystal. Theoretical explanations of the optical behaviour of the crystals based on the arrangement of the structural units in the space lattice have been investigated by E. Mallard, and J. Beckenkamp. H. Haga and F. M. Jäger found that the X-radiograms of boracite above and below the transition point are identical within the limits of experimental error.

A. Kenngott found that powdered boracite, both before and after calcination, is very sparingly soluble in water, to which it imparts an alkaline reaction. W. Heintz, H. Ludwig, and H. Rose showed that the contained chloride cannot be removed from boracite by washing. J. H. van't Hoff has investigated the paragenesis of boracite. K. Kraut found that boracite is slowly soluble in acids; and F. Bischof made a similar observation with respect to stassfurtite. K. Kraut also found that when boiled with a soln. of ammonium chloride, an amount of ammonia is evolved eq. to the contained magnesium oxide.

G. Rousseau and H. Allaire prepared a series of boratochlorides, isomorphous with boracite, by the action of the vapours of metallic chlorides on native calcium borate or boronatrocalcite. The products contained 0·8 to 1·2 per cent. of calcium as impurity. The results with borax in place of the calcium borate were unsatisfactory. W. Heintz's and A. de Gramont's methods for boracite also gave negative results except in the case of zinc. The oxychloroborates are not obtained by the action of the vapours of the metallic chlorides on boracite. If calcium borate or boronatrocalcite be freed from sodium, it does not yield oxychloroborates, showing that the sodium borate is probably converted into the chloride, which then acts as an *agent minéralizateur.* H. Allaire considered that the best way of preparing boracite consists in passing hydrogen chloride over the amorphous borate at a dull red heat. The product is well crystallized. All the chloroborates crystallize in cubes, tetrahedra, and dodecahedra, and they have the pseudo-cubic symmetry and optical characters of natural boracite. The general formula is $6MO.8B_2O_3.MCl_2$, where M stands for an atom of the bivalent element. *Zinc-boracite*, or **zinc hexadecaboratodichloride,** is obtained by the action of the vapour of zinc chloride on borax at a dull red heat; by adding boric acid and a little borax to a fused mixture of zinc and sodium chlorides; and by the wet processes used by W. Heintz, and A. de Gramont for boracite. The salt forms colourless tetrahedra and dodecahedra, of sp. gr. 3·48; and they are very stable. Colourless crystals– chiefly cubes with some tetrahedra and dodecahedra– of *cadmium-boracite,* or **cadmium hexadecaboratodichloride,** were obtained by passing dry chlorine over an intimate mixture of boronatrocalcite and the finely divided metal at a red heat. T. J. Herapath obtained **lead boratodichloride,** $PbCl_2.Pb(BO_2)_2.H_2O$, by mixing conc. soln. of borax, and lead chloride, washing the product with warm water, and drying it over sulphuric acid. The microscopic needles lose water at 200°; and are hydrolyzed by hot water. Yellow tetrahedra and dodecahedra of *nickel-boracite,* or **nickel hexadecaboratodichloride,** were obtained in a similar way. The corresponding *cobalt-boracite,* or **cobalt hexadecaboratodichloride,** forms tetrahedra and cubes which are violet by reflected and green by transmitted light. White cubes of *manganese-boracite,* or **manganese hexadecaboratodichloride,** were formed by the action of chlorine on a mixture of boronatrocalcite and manganese carbide, the product being purified by treatment with conc. hydrochloric acid, and any carbon being separated by means of bromoform and methylene iodide. The case of iron presents special difficulties, because ferrous chloride is not volatile at a sufficiently low temp. Good results are, however, obtained by passing the vapour of ferric chloride over an intimate mixture of calcium borate with a large excess of small pieces of wrought-iron or of steel wire, the mixture being heated at about 330°. Ferrous chloride is formed, and immediately reacts with the borate. The excess of ferrous chloride is dissolved by means of water, and the unattacked iron is easily separated. The *ferrous-boracite,* or **ferrous hexadecaboratodichloride,** so produced forms greyish transparent crystals; it dissolves slowly in nitric acid, and is rapidly decomposed by fused alkali carbonate. T. J. Herapath made fine acicular crystals of monohydrated **lead diboratodichloride,** $PbCl_2.Pb(BO_2)_2.H_2O$, by the action of a conc. soln. of borax on one of lead chloride. The crystals are not appreciably affected by cold water, but they are decomposed by hot water and by nitric acid.

G. Rousseau and H. Allaire prepared a series of **boratobromides** or **bromoboracites** analogous to the boratochlorides, and by similar methods—by the action of bromine on a mixture of metal and boronatrocalcite. W. Heintz's method for boracite is applicable for zinc and magnesium bromoborates. The cubes, tetrahedra, and dodecahedra seem to have the pseudo-cubic symmetry characters of boracite; they have the same general formula, $6MO.8B_2O_3.MBr_2$. Colourless crystals of **magnesium hexadecaboratodibromide** are formed by the action of the vapour of magnesium bromide on calcium borate heated to redness in an atm. of carbon dioxide; **zinc, cadmium, and manganese hexadecaboratodibromides** form white crystals; **ferrous hexadecaboratodibromide** forms greyish-white cubes and octahedra, and is obtained by passing bromine over an intimate mixture of boronatrocalcite with iron wire heated to redness. The crystals are larger the higher the temp., and are mixed with black prisms of ferric borate which can be removed by treatment with cold, conc. hydrochloric acid. Iron boratobromide dissolves slowly in warm nitric acid. The corresponding **cobalt hexadecaboratodibromide** is green by transmitted light, and violet by reflected light; while **nickel hexadecaboratodibromide** is yellow.

H. Allaire prepared a number of **boratoiodides,** or **iodoboracites,** by fusing mol.

proportions of the iodides of sodium and of the metal chosen with boric acid and a small quantity of borax, in a steel crucible on to which is fitted a cover furnished with a small iron exit-tube; this is necessary in order to prevent aq. vapour from the furnace coming into contact with the contents of the crucible. They are analogous with natural boracite in composition and crystalline habit. The general formula is $6MO.8B_2O_3.MI_2$. **Magnesium hexadecaboratodiiodide** is obtained only with difficulty by passing the vapour of magnesium iodide over heated magnesium borate; it is also formed, but in an impure state, by the action of iodine on a mixture of magnesium and its borate heated in an atm. of hydrogen; it forms colourless cubes and tetrahedra. The **zinc hexadecaboratodiiodide** is, however, readily prepared by passing a stream of carbon dioxide laden with iodine vapour over a heated mixture of zinc and zinc borate; the **cadmium hexadecaboratodiiodide** and **manganese and iron hexadecaboratodiiodides** are prepared similarly, and closely resemble the zinc derivative, but the **nickel hexadecaboratodiiodide** is yellow, and the **cobalt hexadecaboratodiiodide,** violet in colour.

H. le Chatelier,[2] and L. Ouvrard prepared a series of boratochlorides and boratobromides of the alkaline earths by fusing together different proportions of boric oxide and the calcium halide in varying proportions with or without lime. He was unable to make the corresponding boratoiodides. When mixtures of a mol of boric oxide and two mols of calcium iodide are fused with varying proportions of lime, crystals of calcium borate are produced with $CaO:B_2O_3$ in the molar ratios 1 : 1, 2 : 1, and 3 : 1. A. Ditte was also unable to make iodo-apatites by means of the iodides of the alkaline earths owing to their ready decomposition; he had better success with the double iodides of the alkalies and alkaline earths.

According to H. le Chatelier, when a mixture of boric and calcium oxides in any proportion is projected into fused calcium chloride, the mass becomes incandescent, a clear soln. is formed which then becomes turbid owing to the separation of triclinic crystals of **calcium orthoboratodichloride,** $Ca_3(BO_3)_2.CaCl_2$. This compound was also made by L. Ouvrard; it is slowly decomposed by alcohol, and rapidly by water and moist air. L. Ouvrard melted a mixture of 0·5 mol of calcium oxide, one mol of boric oxide, and 5 mols of calcium chloride; and obtained arborescent masses of granular crystals of **calcium trimetaboratodichloride,** $3CaO.3B_2O_3.CaCl_2$, or $3Ca(BO_2)_2.CaCl_2$. The same compound is obtained by fusing one part of boric oxide with 8 parts of calcium chloride. The salt is feebly active towards polarized light, and is rendered opaque by water. Lamellæ of calcium borate, $Ca_2B_2O_5$, active towards polarized light, are formed at the same time. L. Ouvrard prepared needles or prisms of **calcium decaboratodichloride,** $3CaO.5B_2O_3.CaCl_2$, showing a feeble longitudinal extinction. The salt is scarcely affected by water or dil. acetic acid, but dissolves in dil. mineral acids. When a mixture of boric oxide and strontium chloride, with or without the addition of not more than one mol of strontia per mol of boric oxide, is fused, long needles of **strontium decaboratodichloride,** $3SrO.5B_2O_3.SrCl_2$, are formed. If the proportion of strontia be increased borates are formed. The crystals show longitudinal extinction, and are unaltered by water or cold dil. acetic acid. L. Ouvrard prepared **barium decaboratodichloride,** $3BaO.5B_2O_3.BaCl_2$, in an analogous manner; he also obtained **calcium decaboratodibromide,** $3CaO.5B_2O_3.CaBr_2$, by fusing a mixture of boric anhydride (1 mol) with calcium bromide (2 mols), with or without the addition of lime (not more than 0·5 mol); it forms needles or prisms showing longitudinal extinction, almost insoluble in dil. acetic acid, but soluble in mineral acids; when the quantity of lime is increased to 1 mol., **calcium trimetaboratodibromide,** $3CaO.3B_2O_3.CaBr_2$, is formed as transparent octahedra or arborescent, crystalline masses, feebly active towards polarized light, very sparingly soluble in water, but readily so in dil. acetic acid; if, however, the proportion of lime be increased to 2 mols or 3 mols, crystals of calcium borate, $2CaO.B_2O_3$, or $3CaO.B_2O_3$, are respectively obtained. L. Ouvrard likewise prepared **strontium decaboratodibromide,** $3SrO.5B_2O_3.SrBr_2$; and **barium decaboratodibromide,** $3BaO.5B_2O_3.BaBr_2$.

§ 25. Boron Sulphides

J. J. Berzelius,[1] observed that boron burns when heated to redness in sulphuric acid vapour, forming a white deposit on the sides, and a grey deposit on the bottom of the containing vessel. The white powder is **boron trisulphide**, B_2S_3, and the grey deposit is a mixture of this and uncombined boron. If the boron be merely heated until it takes fire, and no further application of heat is made, the sulphide which is formed contains an excess of sulphur. When sulphur and boron are melted together, the excess of sulphur can be distilled from the olive-green mixture. H. Moissan pointed out that at 610°, when the combustion is very vigorous, the boron sulphide coats the boron protecting it from further action so that the transformation is incomplete. This was also emphasized by G. Gustavson.

F. Wöhler and H. St. C. Deville, P. Sabatier, and H. Gautier, heated the boron in a stream of hydrogen sulphide. N. D. Costeanu placed the boron in a small boat in a porcelain tube fitted in a tube furnace, Fig. 33. Each end of the porcelain tube is cemented to a wider glass tube; glass plates, *G*, *H*, are cemented to the free ends of the glass tubes so that the inner tube is visible from end to end. The ends of the porcelain tube are cooled by coils of lead tubing, *A*, *B*, through which cold water flows. One glass tube has a side tube through which the thoroughly dried mixture of hydrogen and hydrogen sulphide can be passed. The other end is fitted with glass bulbs, *C*, *D*, *E*, and with a calcium chloride tower, *F*. The apparatus is first dried and cleansed from air by a stream of dry hydrogen; the temp. then raised to 1500°, and the mixture of hydrogen sulphide and hydrogen introduced. The speed of the current of gas should be sufficient to allow some crystals of the sulphide to deposit near *A*, and a white powder collects in the bulbs *C*, *D*, and *E*. If too much hydrogen sulphide be used, the tube will be obstructed by the decomposition of impure sulphide; consequently the hydrogen sulphide must be largely diluted with hydrogen.

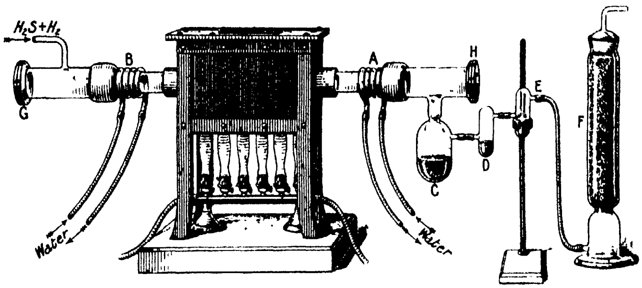

FIG. 33.—The Preparation of Boron Trisulphide.

H. Moissan passed the vapour of dried carbon disulphide over boron at a bright red heat, and found that carbon is deposited in the tube while the boron sulphide is volatilized. J. Hoffmann suggested a cheap method of preparing boron sulphide by passing hydrogen sulphide over commercial manganese or iron boride at 630°–640°, and washing away the excess of sulphur with carbon disulphide. The ferro-boron is more rapidly decomposed and gives a better yield than the mangano-boron. In both cases, only a portion of the contained boron is converted into sulphide. F. Wöhler and H. St. C. Deville made the sulphide by melting boron with lead sulphide: $3PbS+2B=B_2S_3+3Pb$, and H. Moissan found that the sulphides of zinc, arsenic, or antimony acted in an analogous manner at a red heat. E. Frémy, and M. Skoblikoff passed carbon disulphide over boric oxide or a borate mixed with carbon and heated to a high temp.; H. Moissan passed a stream of hydrogen sulphide over amorphous boron heated on a gradually rising temp. to 400° so as to expel the excess of sulphur; and A. Stock and O. Poppenberg obtained boron sulphide by passing a mixture of hydrogen and boron chloride through a tube at a dull red heat; and also by heating sulphometaboric acid, HBS_2, to 300°.

Boron sulphide as a white microcrystalline powder; when sublimed it furnishes white needle-like crystals which, according to E. Frémy, have a sulphurous smell, and affect the eyes. H. Moissan said that the sp. gr. is 1·55; and the m.p., 310°. The molten sulphide solidifies to a glassy mass which, when exposed to air, is more stable than the ordinary form. Boron sulphide volatilizes when heated in a stream of inert gas; P. Sabatier detected volatilization in hydrogen at 300°. The heat of formation, determined by P. Sabatier, is (2B, 3S)=82·6 Cals.; A. Stock and O. Poppenberg gave $2BCl_3+3H_2S=6HCl+B_2S_2-31{\cdot}1$ Cals.; and $2BBr_3+3H_2S$

$=6HBr+B_2S_3+10{\cdot}9$ Cals. P. Sabatier gave for the heat of decomposition in water $B_2S_3+6H_2O_{liquid}=2H_3BO_{3soln.}+3H_2S_{soln.}+57{\cdot}8$ Cals.

E. Frémy noted that a little sulphur is given off when boron sulphide is heated in **hydrogen.** P. Sabatier said that boron sulphide is dissociated in hydrogen at temp. exceeding 300°, forming hydrogen sulphide and boron subsulphide, B_4S. There is some doubt about this because H. Moissan said that, at a red heat, boron trisulphide is not affected by this gas. H. Moissan found that boron sulphide burns with a green flame when heated in **oxygen,** and boric oxide is formed. Boron sulphide absorbs moisture from the air with extreme rapidity, but the glassy form is less speedily affected by moist air. J. J. Berzelius, P. Sabatier, and H. Moissan have emphasized how violently boron sulphide reacts with **water,** forming hydrogen sulphide and boric acid. When the grey sulphide is treated with water, J. J. Berzelius noted that non-sulphurized boron collects as a sediment, while the sulphide with an excess of sulphur deposits milk of sulphur. J. Hoffmann showed that the glassy sulphide is also vigorously attacked by water. According to H. Moissan, boron trisulphide inflames in **chlorine** in the cold, forming boron trichloride and sulphur tetrachloride; if warmed a little, it also reacts with **bromine,** forming boron tribromide and sulphur tetrabromide; but it does not react with melted **iodine;** P. Sabatier said that at a dull red heat boron triiodide is formed. According to H. Moissan, **hydrogen chloride** transforms boron trisulphide at 400° into boron trichloride and hydrogen sulphide; **hydrogen iodide** has no action under these conditions, **sulphur** dissolves in boron trisulphide and some pentasulphide is formed—*vide* infra; boron sulphide forms a complex with **sulphur chloride;** at a red heat, it is not affected by **nitrogen.**

According to H. Moissan, dry **ammonia** is rapidly absorbed with the development of heat, and a yellow powder is formed which becomes white when the temp. is raised, and which with potassium hydroxide gives off ammonia. A. Stock and M. Blix said that if ammonia be liquefied over sulphometaboric acid, HBS_2, and shaken for some hours, a deep yellow soln. is formed; if the ammonia be evaporated at 0°, a yellow liquid remains, which at ordinary temp. gives off ammonia and hydrogen sulphide, forming a solid, possibly **boron hexamminotrisulphide,** $B_2(NH_3)_6S_3$—perhaps identical with H. Moissan's yellow powder. At 104°, it decomposes, thus $B_2S_3.6NH_3=3NH_4SH+B_2(NH)_3$. The reaction with water is not particularly violent, and a yellow soln. is formed. A. Joannis said that the product of the action of ammonia on boron trisulphide is probably a mixture of ammonium hydrosulphide and boramide—*vide* boron trichloride—but A. Stock and M. Blix say that this cannot be the case because it does not lose ammonium sulphide by volatilization at ordinary temp.; it dissolves completely in liquid ammonia, and does not leave a residue of the insoluble borimide.

H. Moissan said that boron trisulphide burns in **nitrogen peroxide,** forming boric oxide and sulphur; it does not react with **phosphorus** at a red heat; it unites with **phosphorus and arsenic chlorides,** forming double chlorides; it is very soluble in phosphorus trichloride, and the soln. deposits fine needle-like crystals—its solubility in phosphorus trichloride is augmented in the presence of sulphur chloride, and the soln. also yields separations such as occur when sulphur chloride is absent. Boron trisulphide does not react with **carbon** or **silicon** at a red heat. N. D. Costeanu said that **carbon dioxide** commences to act on boron sulphide at about 300°, the reaction is faster at higher temp.; sulphur, carbon monoxide, and boric oxide are formed: $B_2S_3+3CO_2=3CO+3S+B_2O_3$. H. Moissan said that boron sulphide decomposes **alcohol** and **ether;** and **organic compounds** generally react with boron trisulphide giving off hydrogen sulphide. It is, however, insoluble in most of the recognized solvents. The metals **potassium, sodium, magnesium,** and **aluminium** decompose boron sulphide, forming the metal sulphide, and may be the metal boride; but **copper, silver, zinc, mercury,** and **iron** do not react.

P. Sabatier found that if boron trisulphide be heated to 300° at one end of a sealed tube, while the other end is cooled by water, boron trisulphide first forms a sublimate of long needles, and behind this appear drops of a colourless liquid which, when cooled for some hours, forms white masses which he considers to be **boron hydrosulphide,** $B(SH)_3$, or $3H_2S.B_2S_3$. A. Stock and O. Poppenberg passed a current of dried hydrogen sulphide into a carbon disulphide or benzene soln. of boron tribromide. The evolution of hydrogen bromide begins at once, but the later stages of the reaction are so slow that it requires about 6 days in order to ensure the complete expulsion of all the bromine as hydrogen bromide. A. Stock and M. Blix suppose the reaction occurs in two stages: (i) A quick reaction between the boron bromide and hydrogen sulphide, forming boron sulphobromide; and (ii) a slow decomposition of the sulphobromide by the hydrogen sulphide. On evaporation of the remaining liquid, long, white, needle-like crystals are obtained. Analyses and mol. wt. determinations in benzene soln. agree with **sulphometaboric acid,** $B_2S_3.H_2S$, or $BS(HS)$, or HBS_2. The compound was also made by J. Hoffmann. It begins to melt in a sealed tube at 120°, and is quite fluid at 135°-140°; it freezes to a white crystalline mass on cooling. The compound is sparingly soluble in carbon disulphide at −20°, but at ordinary temp., 100 parts of benzene or of carbon disulphide dissolve 20 parts of the compound. Sulphometaboric acid smells of hydrogen sulphide, and it slowly loses the last-named gas at ordinary temp. and press., the action is faster in vacuo over sulphuric acid, and faster still if heat be applied—boron trisulphide remains. Water vigorously decomposes the compound into hydrogen sulphide and boric acid; hydrogen sulphide is also evolved when in contact with alcohol and ether—a compound appears to be also formed in the last-named reaction.

A. Stock and M. Blix prepared double compounds of boron sulphide with boron chloride and bromide, by dissolving sulphometaboric acid in an excess of the boron halide, and evaporating to dryness in vacuo. Analyses agree with **boron sulphochloride,** $B_2S_3.BCl_3$, or BSCl, and with **boron sulphobromide,** $B_2S_3.BBr_3$, or BSBr. These compounds are decomposed into their components by heat; and when boiled with carbon disulphide the boron halide is given off.

According to H. Moissan, **boron pentasulphide,** B_2S_5, is obtained by heating boron iodide (20 grms.) with sulphur (rather less than one eq.) in carbon disulphide soln. for 24 hrs. at 60°. The precipitated product is washed with carbon disulphide to remove the iodine. The pentasulphide appears to form a sparingly soluble additive compound with iodine; it cannot therefore be washed quite free from iodine. Boron pentasulphide is a white crystalline powder of sp. gr. 1·85, and m.p. 390°; it is hydrolyzed by water into boric acid, hydrogen sulphide, and sulphur, and resembles the trisulphide in its behaviour with alcohol, the excess of sulphur separating in the free state. It dissociates into the trisulphide and sulphur when heated to its m.p. in a vacuum, and is decomposed in a similar manner when heated with mercury or silver, a sulphide of the metal being formed. It is converted by aq. potassium hydroxide into potassium borate and polysulphide, and is acted on by chlorine at a low temp. with the formation of an unstable crystalline substance. If the individuality of boron pentasulphide be established, it would indicate that boron can function as a quinquevalent element.

§ 26. Boron Sulphates

According to G. Gustavson,[1] boron chloride or bromide reacts with sulphur trioxide in a sealed tube at 120°: $2BCl_3+4SO_3=3SO_2Cl_2+B_2O_3.SO_3$. The white product was not analyzed; it reacts with water, forming boric and sulphuric acids, and when heated in a platinum dish, sulphur trioxide is evolved, and boric oxide remains. The compound has the composition $B_2O_3.SO_3$, and it may be regarded as **boryl sulphate,** $O:B.O.B:SO_4$, or $SO_2(OBO)_2$. Neither R. F. d'Arcy nor A. Pictet and G. Karl could obtain a compound of sulphur and boron trioxide by heating a mixture of the two in open vessels; but the latter obtained boryl sulphate by heating a mixture of boron and sulphur trioxides in a sealed tube at 115°–120°. By working at 230°, **boryl disulphate,** $B_2O_3.2SO_3$, or $BO.O.SO_2.O.SO_2.O.BO$, is formed, and mixtures of the two are obtained at intermediate temp. Both compounds are colourless, amorphous, bulky, brittle, hygroscopic substances, which have no definite m.p., do not fume in moist air, but dissociate when heated, leaving eventually residues of boron trioxide. They dissolve in water, yielding soln. of boric and sulphuric acids. Boryl disulphate reacts with alcohol to form alkyl borates and alkyl-sulphuric acids.

H. Bauer and J. Gyiketta prepared what appeared to be boryl sulphates, $M'(BO)SO_4$, under the trade name *borol*, by gradually adding an eq. of boric acid to an eq. of a fused metal hydrosulphate– *e.g.* $KHSO_4$, or $NaHSO_4$– and heating the mixture to 500°; or by similarly heating a mixture of sulphuric acid, a borate, and a metal sulphate:

$$SO_2{<}^{OH}_{ONa}+HO.B{<}^{OH}_{OH}=2H_2O+SO_2{<}^{O.BO}_{ONa}$$

Sodium borylsulphate, $Na(BO)SO_4$, is soluble in water, and the soln. has an acid reaction. The salt contains less boron than boric acid, but has greater antiseptic properties than the eq. boron; and it has been recommended as a depilatory for hides and skins.

According to H. Davy,[2] boron dissolves in hot sulphuric acid with a slight effervescence, forming a black liquid, which gives a black precipitate with potash-lye. The product has not been further studied. L. Gmelin found boric oxide or acid readily dissolves in sulphuric acid, especially if heated, forming a viscid colourless mass from which boric acid separates on standing. H. Schiff found that water precipitates boric acid or boric oxide. V. Merz stated that a substance with the composition $5B_2O_3.2SO_3.2H_2O$, or $5B_2O_3.2H_2SO_4$, is produced by melting equal parts by weight of boric acid and conc. sulphuric acid, and then warming the product to 250°–280° so as to volatilize the excess of sulphuric acid. A transparent glass is formed on cooling. If heated to 350°–400°, the product is not decomposed, but in some cases nearly all the sulphuric acid was driven off by this treatment. The glass becomes white and opaque on exposure to the air, and moisture is at the same time absorbed. Neither R. F. d'Arcy nor C. Schultz-Sellac could obtain V. Merz's product, for sulphur trioxide was continuously evolved on a rising temp., and the composition of the product is never constant. C. Schultz-Sellac stated that if the soln. of boric acid in sulphuric acid be treated with sulphur trioxide, or if boric oxide be dissolved in fuming sulphuric acid, crystals separate from the liquid. The composition is stated to be $B_2O_3.3SO_3.H_2O$, but since sulphur trioxide is evolved when the product is melted, C. Schultz-Sellac said that the compound is not to be regarded as *boron sulphate*, $B_2(SO_4)_3.H_2O$, but is rather a *boryl sulphate*, $H(BO)SO_4.\frac{1}{2}SO_3$. R. F. d'Arcy failed to obtain this compound, but he found that a violent reaction ensues when finely powdered boric acid is added to a large quantity of sulphur trioxide, and the whole mass liquefies. The product was heated to 100° until sulphur trioxide ceased to be evolved, and on cooling, a solid separated which when dried on porous tiles over sulphuric acid had a composition $B_2O_3.6SO_3.3H_2O$, or $H_3BO_3.3SO_3$, or $B(HSO_4)_3$, **boron hydrosulphate.** It is a white solid with a m.p. 215°; it dissolves readily in fuming sulphuric acid, and is very hygroscopic.

The mineral *sulphoborite* occurs in the Stassfurt salt beds, and was obtained along with anhydrite as a residue in the soln. of the carnallite of Westeregeln. K. Thaddéeff's analysis [3] corresponds with $2MgSO_4.2Mg_2B_2O_5.9H_2O$, or $2MgSO_4.4MgHBO_3.7H_2O$, **hydrated magnesium sulphatoborate.** It forms colourless crystals, may be with a reddish tint, belonging to the rhombic system with axial ratios, according to H. Bücking, $a:b:c=0·6196:1:0·8100$. The sp. gr. is 2·44, and the hardness over 4. The double refraction is negative, and H. Bücking's values for the indices of refraction with sodium light are $\alpha=1·5272$; $\beta=1·5362$; and $\gamma=1·5443$.

§ 27. Boron Phosphates

A. Vogel [1] prepared **boron phosphate,** BPO_4, by the action of a boiling soln. of phosphoric acid on boric acid. The turbid liquid was evaporated to dryness, and the excess of phosphoric acid was removed by washing with hot water. G. Meyer heated the mass to redness before leaching with water, otherwise the product filters with great difficulty. G. Gustavson prepared the same compound by heating boric oxide with phosphoryl chloride, $B_2O_3+2POCl_3=BPO_4+BCl_3.POCl_3$, or boron trichloride with phosphorus pentoxide, $2BCl_3+P_2O_5=BPO_4+BCl_3.POCl_3$, in a sealed tube; the residue should be calcined. Boron phosphate is a white powder which cannot be fused in the blowpipe flame. It is not decomposed by boiling water, or by conc. acids, but it is soluble in a boiling soln. of alkali hydroxide. J. Prescher said that the attack with a boiling dil. soln. of alkali hydroxide is very slow. According to G. Meyer, boron phosphate is decomposed by fused alkali hydroxides or carbonates, or by fused sodium chloride. J. Prescher represents the reaction with fused sodium hydroxide: $BPO_4+3NaOH=NaBO_2+Na_2HPO_4+H_2O$. When heated with sodium, A. Vogel obtained sodium phosphide and a black mass, probably boron phosphide. According to G. Meyer, compounds in which boron plays the *rôle* of base, are usually chemically inert; and J. Prescher emphasized the *rôle* this insoluble compound plays in the analysis of mixtures of phosphates and borates.

M. Prinvault [2] melted equi-molar parts of boric acid and sodium pyrophosphate, and obtained a white mass with the composition $2Na_2O.B_2O_3.P_2O_5$, corresponding with **sodium borylphosphate,** $Na_2(BO)PO_4$. It is decomposed by water or alcohol, forming normal sodium phosphate. The corresponding **potassium borylphosphate,** $K_2(BO)PO_4$, was also prepared.

C. Nöller [3] applied the term *lünebergite* to a **magnesium boratophosphate,** $3MgO.P_2O_5.B_2O_3.8H_2O$, or $Mg(BO_2)_2.2MgHPO_4.7H_2O$, found in the gypsum beds of Lüneberg, Hannover. It also contains 0·7 per cent. of fluorine. The sp. gr. is said to be 2·061. It loses no water at 100°, and is soluble in nitric and hydrochloric acids. W. Biltz and E. Marcus' analysis corresponds with $Mg_3(PO_4)_2.1·75H_3BO_3.6H_2O$. Dehydration curves show that six mols of water are lost at 200°, and the remainder is slowly evolved at 600°. Free boric acid is not present, but microscopic examination does not determine whether the boric acid and magnesium phosphate are in solid soln.

CHAPTER XXXIII

ALUMINIUM

§ 1. The History of Aluminium

SUBSTANCES with a styptic or astringent taste seem to have been designated στυπτηρία, by the Greeks, and *alumen*, by the Romans. Herodotus,[1] *circa* 500 B.C., relates that Amasis, King of Egypt, contributed a thousand talents of στυπτηρία to the people of Delphos as a subscription to enable them to rebuild their temple which had been destroyed by fire; and Dioscorides, near the beginning of our era, mentioned a number of places from which the mineral στυπτηρία could be obtained; and he indicated several varieties, some of which were used in dyeing and in medicine. Aulus Gellius narrates that in the war between the Mithridates and the Romans, 87 B.C., General Archelaus made a wooden turret fireproof by smearing it over with *alumen*, so that all Sylla's attempts to set it in flames proved abortive. The use of alumen for fireproofing wood is mentioned later by H. J. Wecker, and by A. Marcellinus. Pliny also said that a white variety of *alumen* was used for dyeing bright colours, and a dark variety for dark colours; and that *alumen* is coloured black by the juice of the pomegranate. This may be regarded as showing that iron was probably present in *alumen*. Such information as the scholars have gleaned from the ancient writers agrees with the assumption that the different varieties of *alumen* were more or less impure mixtures of aluminium and ferrous sulphates. The derivation of *alumen* is unknown; some obtain it from ἅλμη; others from ἄλειμμα; Isidorus' suggestion that *alumen vocatur a lumine, quod lumen coloribus præstat tingendis*—alumen is so-called from *lumen* because it gives brilliancy to dyes—is improbable.

Pliny said that in his time Egyptian alum was accounted best; and, according to J. P. de Tournefort, and M. G. A. F. Choiseul-Gouffier, the island of Milo was celebrated on account of its *alumen*. According to Strabo, and Diodorus Sicculus, the islands of Lipari and Stromboli contained so much *alumen* that the Romans derived a considerable revenue from the export duty. It is not known when the salt now called *alum* was discovered, but it was no doubt obtained from the East. This alum was regarded as a species of the ancient *alumen*, and since the new alum was better fitted for general use, the name was soon restricted to it alone. In his *De investigatione magisterii*, the, presumably, twelfth-century Geber spoke of an *alumen glaciale* obtained from Rocca, the son of Serapion, who lived after Rhazes; Geber was acquainted only with the impure στυπτηρία of Dioscorides, and J. Beckmann, therefore, inferred that the purer form of alum was not known before the thirteenth century. The Italians first procured their alum from the Levant, and when these countries were captured by the Turks, the Christians were compelled to purchase alum from their enemy. From F. B. Pegolotti, a writer of the fourteenth century, it appears as if the Italians at that time knew only the Turkish alum.

The Italians learned how the salt was manufactured at Rocca di Soria, but the location of this place is not clear. C. Niebuhr suggests that it is probably Edessa in Mesopotamia. Edessa was also called Roha, Raha, Ruha, Orfa, and Roccha. The new alum was at first called *rocca*, a term which the French altered to *alun de roche*, the English into *roche alum* or *rock alum*, and the Germans—*e.g.* M. B. Valentinus—*Rotzalun*. As V. Biringuccio has remarked, the origin of the term *rocca* is not known. J. C. Scaliger refers it to a Greek term, because the salt was extracted from a rock *alumen rupeum* ; M. Mercatus said that alum acquired the name *rocca* from the alum rocks near Tolfa ; while G. W. von Leibniz said that *alumen rocca* was the kind first obtained from Rocca di Soria, and the name was afterwards given to every good species of alum, just as the purer varieties of alum to-day are called *Roman alums.*

P. Bellon has given a description of the alum-works about Constantinople in the fifteenth century ; and he said that in commerce, the alum was called *alumen Lesbium* or *alumen di Metelin.* Another alum-works flourished in the fifteenth century near Phocæa Nova, *i.e.* Foya Nova near Smyrna. F. B. Pegolotti has given a description of the Eastern alum-works of the fourteenth century. According to A. Baumé, M. Ducus referred to alum from Smyrna, and the mode of manufacture was described as follows :

> In Phocis, which lies close to Ionia, there is a mountain abundant in aluminous mineral. The stones found on the top of this mountain are first calcined in the fire, and then reduced to powder by being thrown into water. The water, mixed with that powder, is put into a kettle ; and a little more water being added to it, and the whole having been made to boil, the powder is lixiviated, and the thick part which falls to the bottom in a cake is preserved ; what is hard and earthy is thrown away as of no use. The cake is afterwards suffered to dissolve in vessels for four days ; at the end of which the alum is found in crystals round their edges, and the bottoms of them also are covered with pieces and fragments of like nature. The remaining liquor, which at the end of four days does not harden, is poured into a kettle, more water and more powder are added to it, and being boiled as before, it is put into proper vessels, and the alum obtained in this manner is preserved as an article very necessary for dyers.

J. J. Pontanus, P. Bizaro, A. Giustiniano, and D. Bottone state that alum was first manufactured in Europe by Bartholomew Perdix or Pernix in the island of Ischia about 1460. The earlier date, 1284, given by G. Targioni-Tozzetti, is wrong. An alum-works, north-west of Tolfa near Civita Vecchia, was founded by John di Castro between 1460–70. Pope Pius II. said : *alumen de Tolpha primum fossum est in Italia ;* and he has given a minute history of the discovery ; he also reported that a statue was erected with the inscription " John di Castro, the Inventor of Alum." It has been stated that the evergreen prickly shrub *Ilex aquifolium* induced John di Castro to search for alum since he considered this plant an indication of the presence of alum ; but, as P. S. Boccone and G. Targioni-Tozzetti have pointed out, the plant does not always grow on alum soils, and it grows on soils where there is " not the slightest trace of alum." The Church derived a great revenue from the alum here made. A number of other Italian alum-works are mentioned by A. Baccius, V. Biringuccio, etc. ; they worked in competition with the Tolfa factory, owned by the Church, but finally had to close. According to N. R. Fermosini, religion was employed as a medium to extend the trade, for a papal bull was issued by the pontiff at Rome forbidding the people to purchase alum elsewhere ; even threats of excommunication were made against transgressors. A. Cesalpinus has described the manufacture of alum at the alum-works of Pope Pius II. at Tolfa. F. Bussi said that over 800 persons were employed, and he added that the alum was made in the following manner :

> The stones were first calcined in a furnace ; a large quantity of water was then thrown over them, and when they were dissolved, the water was boiled in great leaden cauldrons ; after which it was poured into wooden vessels, where, evaporating by degrees, the result was alum of the most perfect kind.

According to V. Biringuccio, an alum-works was erected at Almacaron near Carthagena in Spain. Spanish alum-works have been described by D. G. Bowles, and J. Dillon. J. Beckmann says that alum was made at Oberkaufungen (Hesse) in 1554 ; at Commotau (Bohemia) in 1558 ; and at Langenau (Glatz) in 1563. G. Agricola also mentions several other German works. According to G. Jars, an alum-works was erected at Andrarum (Sweden) in 1630. According to A. Anderson, the first alum-works in England was erected at Gisborough (Yorkshire) in

1608. T. Pennant said that T. Chaloner suspected the presence of alum because the trees in the district were tinged an unusual colour. The alum-works at Whitby and the vicinity have been abandoned in recent years. The original process was described by W. Simpson in his *Hydrological essayes, with a brief account of the allom works at Whitby* (London, 1670).

The *alumen* of the ancients was not the same as the ordinary *alum* of to-day; probably the former was aluminium sulphate contaminated with iron sulphate, while alum is a double salt containing potassium sulphate or an eq. sulphate. Alumen was classed with the vitriols—ferrous and cupric sulphates—so that in the thirteenth century alum and vitriol were regarded—by Geber, Albertus Magnus, and the alchemists—as related substances. In the sixteenth century, Paracelsus, in his *De generibus salis*, stated that alum differs from the vitriols because it takes its *corpus* from an intermixture of earths, whereas vitriol takes its *corpus* from the intermixture of metallic *corpora*—whatever that may mean! In 1684, M. Ettmüller[2] discovered that alum is obtained by acting on clay with sulphuric acid; G. E. Stahl, 1702, and J. Juncker, 1730, believed that the unknown base of alum is a *terra calcaria* because it has the nature of lime or chalk; H. Boerhaave adopted the same view. Twenty years later, F. Hoffmann stated his opinion that the base of alum is a true, distinct earth. This view was accepted by C. J. Geoffroy in 1728; by J. Hellot in 1739; and by J. H. Pott in 1746. The last-named chemist called the base *thonichte Erde*, or *terre argilleuse*. In 1754, A. S. Marggraf showed that the earth is a definite substance *sui generis* quite different from lime, that it is contained in all natural clays, from which it can be extracted by sulphuric acid, leaving behind silica, so that the purest white clay contains only silica and the earthy base of alum.

Many chemists supposed that alum earth was a variety of silica. Thus, C. W. Porner, and A. Baumé regarded the earth of alum to be silica; common clay, to be siliceous earth; and alum, to be the same earth supersaturated with sulphuric acid. The subject was also discussed by G. L. L. de Buffon, G. K. C. Storr, J. K. F. Meyer, and J. C. Wiegleb. C. W. Scheele, however, showed that in establishing his conclusion, A. Baumé fused the silica with potassium hydroxide in a fireclay crucible, and the alum was derived from the clay of the crucible.

The presence of an alkali, as well as sulphuric acid and the earthy base, is necessary for the production of alum.

The early philosophers, R. Boyle, and N. Grew, seem to have adopted the opinion that metals could be produced from common earthy substances. J. J. Becher, and G. E. Stahl first indicated the relations of the metals to earthy substances. The term *argil* or *argil pur* was then applied to the earthy base of alum; but L. B. Guyton de Morveau argued that since alum is a *sel alumineux* the proper name for the base is *alumine*; the use of terms like *argille* and *terre argilleux* is confusing and should not be continued. The term *alumine* was thereafter employed in France, and this was anglicized to *alumina* in England, while in Germany the earth of alum is still called *Thonerde*.

Having discovered the acid and one of the bases in alum, it remained to find the second base. G. Agricola, and A. Libavius stated that the soln. from the alum-rock does not crystallize readily unless an alkali is present; and each stated that the general practice was to add decomposed urine to the soln. to facilitate crystallization, so that the alum made by G. Agricola, A. Libavius, J. Kunckel, and F. Hoffmann must have contained ammonia alum. Later, the urine was replaced by potash. Both T. Bergman and C. W. Scheele regarded the presence of potash in alum as an impurity. A. S. Marggraf and G. von Engeström showed that alum contains two bases, and this was further emphasized by A. L. Lavoisier, and A. F. de Fourcroy. L. N. Vauquelin, and J. A. C. Chaptal established by analysis that potash is an essential constituent of ordinary alum, and that that base can be replaced by ammonia; they also showed that alum can be made from alunite without adding potash because the alkali base is already present in the mineral.

In 1758, P. J. Macquer stated his belief that the earth of alum is more or less distinctly related with the metal earths; and soon afterwards, T. Baron showed that the base of alum has some analogies with the metal earths, and has no properties in common with any other known earths. He then tried all known methods of reducing the earth to a metal, but failed. He concluded:

> If I had been fortunate enough to reduce the base of alum to a metal, no other argument would be needed, and that which to-day is conjectured would be a demonstrated fact. I am far from regarding the problem as an impossibility. I think it not too venturesome to predict that a day will come when the metallic nature of the base of alum will be incontestably proved.

In 1782, A. L. Lavoisier said that it is highly probable that alumina is the oxide of a metal whose affinity for oxygen is so strong that it cannot be overcome either by carbon or by any other known reducing agent; and, with prophetic sagacity, he added: *Il seroit possible à la rigueur que toutes les substances auxquelles nous donnons le nom de terres, ne fussent que des oxides métalliques, irréductibles par les moyens que nous employons.* M. de Ruprecht and M. Tondi claimed to have obtained a metal from alumina by heating to a high temp. for 3 hrs., an intimate mixture of alumina and charcoal dust packed in a fireclay crucible, and filled up with charcoal and covered with a layer of bone ash. A. M. Savaresi, and M. H. Klaproth showed that the alleged metal base of alumina was really iron phosphide. There is a report in some encyclopædias that in the time of Tiberius (41 B.C. to 37 A.D.) a metal was made from clay. It was said that the metal had the appearance of, but was lighter than silver, and that it could be wrought like iron. This statement is probably founded on a misinterpretation of Pliny's [3] words —*vide* history of silica.

H. Davy [4] tried to isolate the metal by electrolyzing a mixture of alumina and mercuric oxide, but without result; he then passed the current through a fused mixture of alumina and potassium hydroxide, and obtained a metallic deposit which was decomposed by water giving a soln. which contained alumina. The deposit was apparently a mixture of alkali metal and aluminium, but he was unable to isolate the latter; similarly with the action of potassium on alumina. By fusing iron in an electric arc in contact with alumina, he showed that the iron is alloyed with aluminium. He obtained a similar alloy by heating a mixture of alumina, potassium, and iron filings. H. Davy added: "Had I been fortunate enough to isolate the metal after which I sought, I would have given it the name *alumium;*" but later on, influenced by the argument that the metal should be named after the oxide, so that the stem word should be *alumin*, he used the term *aluminum*—later writers have adopted the more euphonious *aluminium*.

B. Silliman fused alumina on charcoal before the oxy-hydrogen blowpipe flame, and noted small metallic globules darting and rolling from under the fused mass, and burning with a bright light. The globules were presumably aluminium, which burnt instantly so that no globules of metal could be obtained. In 1824, H. C. Oersted reported that he had isolated aluminium by the action of potassium amalgam on aluminium chloride; and distilling the mercury from the product. It has been questioned if aluminium, or an alloy of potassium and aluminium, was obtained. I. Fogh. however, claims that by this process H. C. Oersted did prepare aluminium for the first time, and said that it is a metal with the colour and lustre of tin; and exhibited a sample of the metal in April, 1825, before the Danish Scientific Society. In 1809, J. J. Berzelius wrote to H. Davy that he had reduced alumina by heating it with carbon and iron, but since no reference is made to aluminium prepared by this process in J. J. Berzelius' later writings, it is assumed that he must have found that he had been mistaken. J. J. Berzelius tried to get aluminium by the action of potassium on cryolite, but later knowledge showed that he used an excess of potassium, and so obtained an alloy which decomposed in water; had he used an excess of fluoride, he would have obtained the metal. In 1827, F. Wöhler obtained the metal as a grey powder by the action of potassium on the chloride; and H. St. C. Deville obtained the metal by reducing the chloride with sodium. He also tried reducing aluminium compounds with carbon; and, almost simultaneously with R. Bunsen, he isolated the metal by electrolysis.

The cost of H. St. C. Deville's early experiments was met by a grant from the French Academy of Sciences. In 1855, a large bar of aluminium was exhibited at the Palais de l'Industrie, docketed with the sensational name *l'argent de l'argile.* In 1854, a medal of aluminium was struck and presented to Napoleon III. The Emperor hoped to apply such a light metal to the armour and helmets of the French cuirassiers, and he authorized experiments to be made on a large scale at his expense. Large-scale experiments were made at Javel with the assistance of C. and A. Tissier, who were subsequently reproached by H. St. C. Deville with having acted in bad faith in claiming patents and with starting a works at Rouen in which Deville's sodium processes were to be applied. H. St. C. Deville had a plant for producing aluminium erected at Glacière, and this was subsequently removed to Nanterre. Other plants were installed at a number of general chemical works. Between 1859–65, a works used Deville's process at Battersea (London), and between 1860–74, a works used the same process at Washington (Newcastle-on-Tyne). Several improvements were made in Deville's process by J. Webster, H. Y. Castner, etc.

The first pencils of aluminium made by H. St. C. Deville were obtained by electrolysis, but the use of a battery as the source of the current was far too costly to permit its industrial exploitation. Consequently, H. St. C. Deville confined himself to the use of the alkali metals. Meanwhile, great advances had been made in dynamo-electric machinery. This gave an impetus to the electrolytic processes of R. Bunsen, and H. St. C. Deville. Thus, R. Grätzel in 1883, and E. C. Kleiner in 1886, devised industrial electrolytic processes, but these were not very successful until C. M. Hall, and P. V. L. Héroult had developed their method based on the electrolysis of soln. of alumina in molten cryolite—*vide infra*. In illustration of the rise of the aluminium industry, the price fell from 1000 francs per kgrm. in the spring of 1856 when the metal was a chemical curiosity, to 300 francs per kgrm. in August, 1856, to 130 francs per kilo in 1862. In 1895, the price was 1*s.* 5*d.* per lb. The lowest price in 1913 was £81 per ton, and the highest, £85 per ton; during the war the price in 1917 rose to £225 per ton; and in 1919, the average price was £150 per ton. J. W. Richards' estimate of the World's production of aluminium in metric tons from 1913–19 is shown in Table I.

TABLE I.—THE WORLD'S PRODUCTION OF ALUMINIUM (IN METRIC TONS).

Year.	Austria.	Canada.	France	Germany.	Great Britain.	Italy.	Norway.	Switzerland.	United States.	Total.
1913	5,000	5,916	15,000	800	10,000	874	2,500	10,000	29,500	79.590
1914	4,000	6,820	12,000	800	8,000	937	2.500	10,000	40,500	84,957
1915	2,500	8,490	7,500	2,000	6,000	904	3,500	12,500	45,000	88,394
1916	5,000	8,800	20,000	8,000	4,000	1,126	6,000	15,000	63,000	130,626
1917	5,000	11,800	20,000	15,000	6.000	1,740	8,000	15,000	90 700	173,240
1918	8,000	15,000	20,000	25,000	14,000	1,715	7,500	15,000	102,000	208.215
1919	5,000	15,000	15,000	15,000	10,000	4.000	4,000	15,000	90,000	173,000

§ 2. The Occurrence of Aluminium

Aluminium does not occur on the earth's surface in the metallic state. M. Stocker[1] was wrong in stating that aluminium occurs in shining scales in the formations near St. Austell (Cornwall). The combinations of aluminium with oxygen,

fluorine, silicon, etc., are lavishly distributed; they form large mountainous masses; they are the bases of clays and soils. Attempts have been made by F. W. Clarke to calculate the average composition of the earth's lithosphere, from data furnished by A. Harker, A. Knopf, H. S. Washington, etc. Alumina comes second in the list showing the relative abundance of the oxides; silica comes first, and ferrous oxide third.

	Igneous rocks.	Shales.	Sandstones.	Limestones.	Weighted average.
SiO_2 . . .	59·83	58·10	78·33	5·19	59·77
Al_2O_3 . . .	15·02	15·40	4·77	0·81	14·89
Fe_2O_3 . . .	2·62	4·02	1·07	0·54	2·69
FeO	3·43	2·45	0·30	—	3·39

Aluminium is more abundant than any other metal; it comprises nearly 8 per cent. of the earth's crust. Aluminium is nearly twice as abundant as iron. The average elemental composition of known terrestrial matter—including the lithosphere and hydrosphere—starting from the most abundant, is:

	Lithosphere (95 per cent.).	Hydrosphere (7 per cent.).	Average, including atmosphere.
Oxygen	47·33	85·79	50·02
Silicon	27·74	—	25·80
Aluminium . . .	7·85	—	7·30
Iron	4·50	—	4·18

Other estimates have been made by J. H. L. Vogt, J. F. Kemp, etc. Expressing these data in terms of the percentage numbers of atoms in the half-mile crust, ocean, and atmosphere, we have:

O	H	Si	Al	Na	Mg	Ca	Fe
53·81	16·30	15·87	4·68	1·72	1·61	1·40	1·29

H. A. Rowland[2] found the relative order of the intensity of the spectral lines of the elements in the sun is K, Fe, H, Na, Ni, Mg, Co, Si, Al, Ti, Cr, . . . The subject has been discussed by J. N. Lockyer, and A. Cornu. The fortuitous occurrence of aluminium in old bronzes has been examined by E. Nauck, L. C. Marquart, and J. J. Nöggerath.

The most important aluminiferous minerals, from the point of view of the extraction of the metal, are bauxite, and cryolite. Native alums usually occur in out-of-the-way places, and the deposits are comparatively small. Some of the aluminiferous minerals have so fine a lustre and colour that they are included in the lists of precious stones—*e.g.* the ruby, sapphire, turquoise, topaz, garnet, etc.

The aluminium minerals include the **oxides:** *corundum*, Al_2O_3, with the varieties *ruby* and *sapphire*. The **hydroxides:** *gibbsite* or *hydrargillite*, $Al(OH)_3$; *bauxite*, $Al_2(OH)_4O$; *diaspore*, $Al_2(OH)_2O_2$; *völkerite*, approximating $Al(OH)_3.3Mg(OH)_2.3H_2O$; and *namaqualite*, approximating $Al(OH)_3.2Cu(OH)_2.2H_2O$. The **aluminates:** *spinel*, or *magnesia spinel*, or *spinel ruby*, $Mg(AlO_2)_2$; *hercynite* or *iron spinel*, $Fe(AlO_2)_2$; *pleonaste* or *magnesia iron spinel* $(Mg, Fe)(AlO_2)_2$; *chrome spinel* or *picotite*, $(Mg, Fe)(Al, Fe, Cr)_2O_4$; *zinc spinel* or *gahnite*, $Zn(AlO_2)_2$; *dysluite*, $(Zn, Mn)(Al, Fe)_2O_4$; *chrysoberyl*, and *alexandrite*, $Be(AlO_2)_2$. The **halide salts:** *fluellite*, $AlF_3.H_2O$; *cryolite*, $3NaF.AlF_3$; *chiolite*, $5NaF.3AlF_3$; *parchnolite*, and *thomsenolite*, $AlF_3.NaF.CaF_2.H_2O$; *gearksutite*, $Al(F, OH)_3.CaF_2.H_2O$; *prosopite*, $2Al(F, OH)_3.Ca(F, OH)_2$; and *ralstonite*, $3Al(F, OH)_3.(Na_2, Mg)F_2.2H_2O$. The **sulphates:** *alum*, $(NH_4, K, Na)Al(SO_4)_2.12H_2O$; *kalinite*, $KAl(SO_4)_2.12H_2O$; *tschermigite*, $NH_4Al(SO_4)_2.12H_2O$; *mendozite* is an impure soda-alum, ideally $NaAl(SO_4)_2.12H_2O$; *pickeringite*, or magnesia-alum, $MgAl_2(SO_4)_4.22H_2O$; *picroalumogen*, $Mg_2Al_2(SO_4)_5.22H_2O$; *apjohnite*, manganese-alum, $MnAl_2(SO_4)_4.22H_2O$; *bosjemanite* is a mixture of magnesia alum and manganese sulphate; *dietrichite* is a mixture of manganese-zinc alum; *halotrichite*, $FeAl(SO_4)_2.12H_2O$; *keramohalite*, or *alunogen*, $Al_2SO_4.18H_2O$; *aluminite*, $(AlO)_2SO_4.9H_2O$; *alumian*, $Al(AlO)(SO_4)_2$; *alunite*, $K(H_2AlO_2)_3.(SO_4)_2.3H_2O$; *zinc aluminite*, $(AlOH)SO_4.Zn_3(AlO_2)_2.8H_2O$; *cyprusite*, $(FeO)_7Al(SO_4)_5.7H_2O$; *felsöbanyite*, $Al_2(SO_4)(OH)_4.2Al(OH)_3.5H_2O$; *paraluminite*, $Al_2(SO_4)(OH)_4.2Al(OH)_3.10H_2O$; *sonomaite*, $3MgSO_4.Al_2(SO_4)_3.33H_2O$; *dumreicherite*, $4MgSO_4.Al_2(SO_4)_3.36H_2O$; *plagiocitrite*, $(Al, Fe)_2(Fe, Mg, Ni, Co)(K, Na)(OH)_6.21H_2O$; *clinophäite*, $(Al, Fe)_2(Fe, Mg, Ni, Co)(K, Na)_8(OH)_6(SO_4)_5.5H_2O$; *voltaite*, $(Al, Fe)_4(Fe, Mg)(K, Na)_2(OH)_2(SO_4)_{10}.14H_2O$; *ettringite*, $Al_2Ca_6(OH)_{12}(SO_4)_3.24H_2O$; *lettsomite*, or *cyanotrichite*, $Cu_2Al_2(OH)_4(SO_4)_3Cu_3(AlO_3)_2.5Cu(OH)_2.13H_2O$; and *woodwardite*, $Cu_2Al_2(OH)_4(SO_4)_3.Cu_6(AlO_3)_4.Cu_8(OH)_2.18H_2O$. The **carbonates:** *dawsonite*,

$NaAl(OH)_2CO_3$; and *mellite*, $Al_2C_{12}O_{12}.18H_2O$. The **phosphates**: *minervite*, $AlPO_4.7H_2O$; *amblygonite*, or *montebrasite*, $LiAl(F,OH)PO_4$; *augelite*, $Al_2(OH)_3PO_4$; *trolleite*, $Al_4(OH)_3(PO_4)_3$; *lazulite*, $(Mg, Fe, Ca)(AlOH)_2(PO_4)_2$; *cirrolite*, $Ca_3Al_2(OH)_3(PO_4)_3$; *tavistockite*, $Ca_3Al_2(OH)_6(PO_4)_2$; *berlinite*, $AlPO_4.\frac{1}{2}H_2O$; *variscite*, or *callaite*, $AlPO_4.2H_2O$; *barrandite*, $(Fe, Al)PO_4.2H_2O$; *callainite*, $AlPO_4.2\frac{1}{2}H_2O$; *zepharovichite*, $AlPO_4.3H_2O$; *gibbsite*, $AlPO_4.4H_2O$; *wavellite*, $(AlOH)_3PO_4.4\frac{1}{2}H_2O$; *kalaite* or *turquoise*, $Al_2(OH)_3PO_4.H_2O$, or $Al_2(OH)_4HPO_4$; *peganite*, $Al_2(OH)_3PO_4.1\frac{1}{2}H_2O$; *fischerite*, $Al_2(OH)_3PO_4.2\frac{1}{2}H_2O$; *evansite*, $Al_3(OH)_6PO_4.6H_2O$; *eosphorite*, $MnAl(OH)_2PO_4.2H_2O$; *childrenite*, $FeAl(OH)_2PO_4.H_2O$, or $(Fe'', Mn, Ca) Al(OH)_2PO_4.H_2O$; *henwoodite*, $Al_4CuH_{10}(PO_4)_8.6H_2O$; *chalcosiderite*, $Cu(Fe''', Al)_2(Fe'''O)_4(PO_4).8H_2O$; *goyazite*, $Al_{10}Ca_3P_2O_{23}.9H_2O$; *hitchcockite*, $Al_4PbP_2O_{12}.9H_2O$; and *svanbergite*, $(AlO)_6(CaOH)Na_3(PO_4)_2(SO_4)_2.3H_2O$. The **arsenates**: *durangite*, $Na(AlF)AsO_4$; *synadelphite*, $Mn_5Al_2(OH)_{10}(AsO_4)_2$; *hæmatolite*, or *diadelphite*, $Mn_4Al(OH)_8AsO_4$; *liskeardite*, $(Al, Fe)AsO_4.8H_2O$; and *liroconite*, or *linsenerz*, $Cu_9Al_4(OH)_{15}(AsO_4)_5.20H_2O$. The **borates**: *jeremejeffite*, $AlBO_3$ or $(AlO)BO_2$; and *rhodizite*, $KAl_2B_3O_8$, or $K(AlO)_2(BO_2)_3$. The **silicates** or **aluminosilicates** include *felspars*, *micas*, *clays*, *sillimanite*, *cyanite*, *garnet*, etc.—*vide* the silicates.

Many natural waters contain alumina, and particularly those in volcanic districts. Thus, C. du Ponteil[3] found 0·3546 per cent of aluminium sulphate, $Al_2(SO_4)_3$, in the clear, yellow, very acid water of a hot-lake on White Island (Bay of Plenty, N.Z.); W. Skey, and J. S. Maclaurin have also analyzed the water from the same locality. S. de Luca found 0·335 grm. of alumina per litre in the solfatara waters of Pozzuoli. J. B. J. D. Boussingault reported 1·66 parts per 1000 in the water of the thermal spring at Paramo de Ruiz (New Granada). W. B. Markownikoff reported 13·27 per cent. of aluminium sulphate in the salt deposited on the shores of Lake Djouvan-Tubé (Akmolink Province, Russia). J. K. Crook reported on the aluminiferous spring water of the United States:

> This substance is found in springs in the form of the oxide, or alumina, and of the sulphate. It occurs in variable quantities, ranging from a mere trace to sixty or eighty grains per gallon, as seen in some of the Virginia alum springs. The sulphate is almost always present in the sulphuretted chalybeate waters, and, as stated above, in the acid springs. The internal use of alum waters is generally governed by these associated ingredients. Some of the alum springs have acquired a considerable reputation in scrofulous diseases and in chronic diarrhœa and dysentery. The iron-alum waters are beneficial in passive hemorrhages and in exhausting night-sweats. Locally their astringent action calls them into service in much the same class of cases as are benefited by the acid waters. They have produced valuable results in conjunctivitis, stomatitis, chronic vaginitis, and other relaxed or inflammatory states of those portions of the mucous surfaces accessible to local treatment. They have also been found to act as a useful auxiliary in the treatment of ulcerated surfaces, abrasions, etc. In large quantities alum waters have a laxative influence, but they are seldom used in virtue of this action.

A. C. Peale's report of the composition of the mineral waters of the United States shows the presence of up to 226·41 grains of alumina per gallon; this quantity was reported in the water of the Iowa Acid Spring. C. F. Langworthy and P. T. Austen have compiled reports of nearly 500 determinations of alumina in natural waters in different parts of the world.

A small proportion of aluminium is found in the ashes of numerous plants, but, so far as is known, this element is not essential for plant growth, and G. Cugini[4] considers that it may be regarded as an accidental constituent. Most soils contain traces of aluminium phosphate, and, according to J. Lewitsky, aluminium phosphate is slightly soluble in soil soln., and hence alumina is carried into the plant sap and distributed to the different parts. L. Ricciardi concluded that the assimilation of alumina by the plant does not depend on the percentage of alumina in the soil, and that, generally speaking, alumina is most abundant in the trunk and branches, less so in the husks and seeds, and least of all in the leaves. W. Knop said that the lycopodiaceæ secrete organic acids, and contain oxalic acid which dissolves alumina and ferric oxide. D. D. Jackson found that alumina is precipitated from natural waters by the *crenothrix* (bacteria), and that about one-third of the dried organism consists of alumina. It is not known how the alumina is combined in the plant. H. Yoshida thought that in the lacquer tree (*rhus vernicefera*) alumina is present as an aluminium arabate. H. G. Smith found a deposit of a basic aluminium succinate, $Al_2(C_4H_4O_4)_3.Al_2O_3$, in the centre of a silky oak tree (*orites excelsa*) from Queensland; and he suggested that the alumina was present in the sap as aluminium malate. L. N. Vauquelin has stated that he found aluminium acetate in the sap of the birch. He considered the deposit represented a natural effort to get rid of a surplus of alumina not needed by the tree. In the analyses by J. C. Bell, the alumina in the plant ash was reported as aluminium phosphate. O. L. Erdmann assumed that the alumina is free in the ashes of woods and seeds. H. Coupin found that the presence of one part of aluminium sulphate in 50,000 parts of distilled water is toxic to the roots of wheat, for the plant is injured but not killed. M. Wypfel found aluminium chloride to have a toxic effect on seedlings of corn, bean, pea, cucurbit, sunflower, beet, and onion, when the plants are watered daily with a 0·5 or 1·0 per cent. soln. A. Chassevent and C. Richet found that the order of toxicity of metal salts on the lactic ferment is: Mg, Li, Ca, Sr, Ba, Al, Mn, Fe, Pb, Zn, Ca, Cd, Pt, Hg, Ni, Au, Co. Lists of the occurrence of alumina in plants have been given by C. F. Langworthy and P. T. Austen, by F. Czapek, and by G. Stoklasa.

A. W. Blythe[5] is of the opinion that cleaned *wheat* contains no alumina, and that particles of clay and sand from the mill-stones find their way into the flour so that no second-class flour in commerce is free from a small percentage of alumina. J. C. Bell reported up to 0·017 per cent. of aluminium phosphate in the ash of wheat; up to 0·0204 per cent. of aluminium phosphate in the ash of *flour*; and up to 0·011 per cent. of aluminium phosphate in *bread* free from alum. A. H. Allen said that aluminium is a normal constituent of wheat in amount corresponding with " 8 grains in a 4-lb. loaf of bread." A. Dupré, M. D. Penney, G. L. Teller, J. A. Wanklyn and W. J. Cooper, G. Wellborn, W. C. Young, C. Councler, T. J. Herapath, and H. Yoshida have reported on the aluminium content of flour. A. Béchamp[6] found alumina in *yeast*; C. H. Lawall, C. G. Wheeler, J. Lerner, H. Watts, and G. E. Colby, in *hops*; W. Baer, in *rape* and rape-seed; E. H. S. Bailey, in *corn-cobs*; J. T. Way and G. H. Ogston, and C. Councler, in *rye*; F. W. Dafert, in *panic grasses* (panicum); T. J. Herapath, in *oats*; J. Stoklasa, H. Yoshida, J. Lerner, in *barley*; F. Vielguth, in *straw* (*galium mollugo*); and H. Yoshida, in *millet*, *rice*, and *buckwheat*; and F. Apoiger, and O. Habermann, in *maesa picta*. J. C. Bell[7] found from 0·05 to 3·850 per cent. of aluminium phosphate in the ash of pure *grape juice*; and from 0·377 to 3·956 per cent. in the ash of fermented and unfermented *wines*. L. Gabba said that wines do not contain aluminium in excess of 0·01 per cent. R. Kayser added that the presence of 0·3-0·4 grain of alumina per litre in wine cannot safely be taken as a proof that alum has been added because it takes into soln. during its course of manufacture some alumina. This is especially the case when the wine has been cleared with china clay, as some wines dissolve small amounts of the china clay, and hence contain alumina in the form of a soluble salt. L. l'Hote, M. Minas, J. Moritz, L. Ricciardi, E. Demarçay, W. Hadelich, F. Guerrieri, G. F. Walz, E. Rotondi, F. Sestini, etc., have reported on this subject. The occurrence of aluminium in *club mosses* (*lycopodiaceæ*) has been reported by A. Aderholdt,[8] A. H. Church, C. Councler, W. Knop, A. Langer, W. F. Salm-Horstmar, H. Ritthausen, G. Solms-Laubach, and W. Pfeffer; in *cryptogams*—mosses, ferns, equisetum, etc.—by A. H. Church, G. Mariani, and A. Mayer. L. P. Brown,[9] A. K. Dambergis, F. M. Brandt, and J. R. McD. Irby and J. A. Cabell, and A. P. Smith found alumina in *tobacco*; W. Athenstead, J. H. M. Clinch, and P. Schriddl, in *tea*; P. S. Clarkson, in *cocoa*; and H. Ludwig, in *coffee*. Aluminium has been reported in *sumach* by F. P. Dunnington,[10] and H. W. Harper; in *sassafras*, by F. P. Dunnington; and F. J. Malaguti and J. Durocher reported analyses of the ash of 115 wild plants. F. P. Dunnington found alumina in *brown sedge*, *wire-grass*, *blue thistle*, *potato-weed*, *purslane*, *ragweed*, *mullein*, *dock*, and *stick-weed*. Alumina was found in *anatto* (*bixa*) by A. E. Ebert, and A. H. Hassall; in *sarsaparilla*, by A. B. Griffiths, and H. Ludwig; in *cardamon*, by A. B. Griffiths, and H. B. Yardley; in *chine* and *rhatany*, by A. B. Griffiths; in *red pepper*, by B. von Bitto; in *pepperwort*, by H. Trimble and H. J. Schuchard; in *cinnamon*, by M. Schäzler; in *kousso* (*brazera*), by E. Harms; in *lac* (*rhus vernicefera*), by H. Yoshida; in *plantain*, by E. Harms, and J. F. Strawinski; in *chickweed*, by E. Harms; in *spurge*, by G. C. Wittstein; in *ophelia*, by H. Höhn; in *rupture-wort* (*herniaria*), by G. C. Wittstein; in *millingtonia*, by H. Hollandt; in *dog-bane*, by A. Jessler; in *lichens*, by W. Knop, C.H. Weigelt, and G. C. Wittstein; in *Spanish moss*, by S. de Luca; in *mosses* (*fontinalis*), by R. Strohecker, and G. C. Wittstein; in *sea-weeds*, by E. Mitscherlich, J. Percival, and F. Sestini; in *algæ*, by K. Petter; in *ferns*, by C. Struckmann; in *buttercups*, by G. Ruge[11]; in *dandelions*, by C. H. Lawall, L. E. Sayre, and M. Winternitz; in the *poppy*, by C. J. H. Warden; in the *golden seal*, by R. Gaze; in the *primrose*, by G. C. Wittstein; in the *heather*, by G. C. Wittstein, and E. Wolff; in the *shepherd's purse*, by F. Daubrawa; in the *geranium*, by C. H. Lawall; in the *rhododendron*, by T. de Saussure; in the *pink* (*dianthus*), by R. Andreasch; in the *hyacinth*, by A. Tschirch; in the *sunflower*, by G. C. Wittstein; in the *rose* (*rosa*), by R. Andreasch; in the *star anise*, by C. E. Schlegel; in the *cuckoo-pint*, by C. Rode; in the *Virginian creeper*, by G. C. Wittstein; in the *colchicum* or *autumn crocus*, by C. Reithner; in the *bryony*, by C. F. Heller; in the *thrift* or *sea-pink*, by A. Volcker; in the *boletus*, by K. Fritsch; in *poke-weed* (*phytolacca*), by G. B. Frankforter; in *ivy*, by H. Block; in *poison ivy*, by J. Khittel; in *aralia*, by W. R. Munroe; in *hemlock*, by E. S. Bastin and H. Trimble; in *water hemlock*, by R. Glenk; in *wormwood*, by C. Eylerts; in *gastrolobium bilobum*, by H. Fraas; in *petalostigma quadriloculare*, by C. Falco; in *symploccæ*, by E. Kratzmann; in *jute*, by E. J. Bevan and C. F. Cross; in *hemp*, by A. Bobierre; in *flax*, by R. J. Kane; in *eel-grass* (*zostera*), by E. Baudrimont; in *alfalfa*, by M. Berthelot and G. André, and P. von Gasparin; in *Bermuda grass*, *convolvulus*, *lupine*, and *linden*, by M. Berthelot and G. André; in *peas*, by T. Bromeis; in *red clover* and *blood-root*, by C. H. Lawall; in *yams*, by T. J. Herapath; in *potato*, by C. Councler; in *beet*, by C. Eylerts; in the *banana*, by A. Hébert; in *horse-bean* and *eddoes* or *taro*, by T. J. Herapath; in *tayuya* (*trianosperma*), by D. Parodi; *stereo caulon vesuvianum*, by M. Coppola; in *fruit-juices*, by R. Kayser;[12] in *raspberry*, by C. F. Bergstrand; in *apple*, by C. A. Browne; in *cider*, by R. E. Doolittle and W. H. Hess; in *plum*, by W. Tod; in *pomegranate*, by E. Speiss; in *sloe* or *black thorn*, by E. Schreiner; in *cherry*, by W. Keim; in *fig*, by G. C. Wittstein; *blue-berries*, by R. Kayser; in *rhubarb*, by R. Brandes;[13] in *prickly chaff* (*achyranthes*), by C. J. H. Warden; in *prickly-pear*, by W. W. Light, and L. Ricciardi; in *orange*, by O. Huischke, and L. Ricciardi; in *hydrangea*, by C. H. Lawall, and C. S. Bondurant; in *colts-foot*, by C. S. Bondurant; in *thapsia*, by M. Yvon; in *antherosperma*, by N. Zeyer; in *soya-bean*, by H. Yoshida; in *bread-fruit*, by L. Ricciardi; in *almond*, by L. Ricciardi; in *chestnuts*, by E. Dieterich; in *horse-chestnut*, by E. Staffel; in *paw-paw*, by T. Peckolt; in *guarana*, by T. Peckolt, and C. H. Lawall; in *pareira*, by F. A. Ringer and E. Brooke; in *truffles*, by A. Chatin,[14] and A. Pizzi; in *edible fungus*, by P. Nettlefold; in *boletus*, by J. Wolff; in *morell*, by A. Pizzi; in *sycamore*, by C. Councler;[15] in *lilac*, by C. Councler, and G. C. Wittstein; in *beech*, by C. Councler, and G. C. Wittstein; in *gentian*, by C. Councler; in *bloody-eye*, by C. Councler; in *holly*, by C. Reithner; in *adder's tongue*, by C. Councler; in *mistletoe*, by C. Councler; in *coniferæ*, by E. S. Bastin and H. Trimble, C. Karmrodt, H. Krutzsch, and R. Weber and E. Ebermayer; in *Scotch pine*, by C. Councler, E. Demarçay, C. Karmrodt, K. Kresling and G. C. Wittstein; in *white pine*, by R. Weber and E. Ebermayer; in *Scotch fir*, by E. Demarçay, and C. Karmrodt; in *silver fir*, E. Demarçay; in *eucalyptus*, by W. Smith; in *oak*, by E. Demarçay; in *prickly ash*, and in *elm*, by C. H. Lawall; in *silky oak*, by J. H. Maiden and H. G. Smith; in *birch*, by W. A. E. Witting, and G. C. Wittstein; in *poplar*, by E. Demarçay; in *plane-tree*, by G. M. Tucker and B. Tollens; in *hornbean*, by E. Demarçay; in *myrtle*, by J. W. England; in *honeysuckle*, by J. B. Enz; in *elder*, by L. Huber, and G. C. Wittstein; in *larch*, by C. Karmrodt; in *laurel*, by H. Matusou; in *willow*, by E. Reichardt; in *cane sugar*, by J. W. MacDonald,[16] A. Payen, and W. Wallace; in *beet sugar*, by J. W. MacDonald; in *honey*, by G. von Bungo; in *corn cockle*, by T. Crawfurd; in *cockle-burr* (*xanthium*), by R. Godeffroy; in *ergot*, by J. C. Hermann, G. Ramdohr, and S. von Thielau; in *morphine*, by L. F. Kebler; in *opium*, by C. J. H. Warden; in *cinchonine*, by D. Hooper, G. Lindenmayer, and C. H. Lawall; in *belladonna*, by F. Muck, and C. H. Lawall; in *china*, by E. Reichardt; in *aconite*, by D. von Wasowicz, and C. H. Lawall; and in *legen*, by H. Wefers-Bettink. C. H. Lawall found alumina in *calumba*, *castanea*, *chimaphila*, *calisaya*, *digitalis*, *frangula*, *gelsemium*, *glycyrrhiza*, *hydrastis*, *hyoscyamus*, *jalap*, *kola-nut*, *piscidia erythrina*, *choke-cherry*, *cascara*, *ruta herba*, *sabadilla*, and *hellebore*.

E. Staffel[17] found alumina in veal and in beef; R. Theile, in egg albumen; M. Thezard, in the tibia of an adult mummy from an Egyptian tomb. T. M. Rotch reported 0·37 per cent. of ferric oxide and alumina in the ash of woman's milk, and 0·44 per cent. in the ash of cow's milk. E. Dieterich found 1·398 per cent. of alumina in the ash of cochineal, and C. Liebermann assumed that carmine is an "aluminium-calcium-protein compound of the colouring matter." A. Heyl found alumina in sponge; J. Mayrhöfer, and A. Müntz, in leather; W. McMurtie, 19·88 per cent. of alumina in the excrement of the common bat; R. Schütze, in the mantle of the *phallusia mamillaris*; and G. Walter, in the outer covering of the *protopterus annectens*.

§ 3. The Preparation and Production of Aluminium

A very large number of processes[1] have been devised for the production of aluminium, but few have attained any industrial importance. Some have been worked for a time on a large scale, but have succumbed in the competition against cheaper and more economical processes. Some schemes could have been proposed only by those possessing an inadequate knowledge of chemistry. The only successful process is the electrolysis of a soln. of alumina in a bath of molten fluoride. The different methods which have been proposed have usually been the subject of a patent; nevertheless, nearly all have proved to be either chemically impossible or commercially impracticable. Consequently, the literature of aluminium production is largely a series of sign-posts indicating: No Thoroughfare. The different proposals may be classified: I. Chemical methods involving reduction with (*a*) an alkali metal, (*b*) by some metal other than the alkali metals, and (*c*) by some other reducing agent. II. Electrothermal processes in which the current plays the part of heating agent. III. Electrolytic processes including (*a*) the electrolysis of aq. soln. of aluminium salts, or (*b*) the electrolysis of molten aluminium compounds. IV. Combination of the electrothermal and electrolytic processes in which the heat required for maintaining the charge in a state of fusion is derived from the current itself within the electrolytic cell. This idea was filed as a patent by C. S. Bradley in 1883, which was granted in 1891.

The production of aluminium by chemical processes.—In 1824, H. C. Oersted[2] reduced aluminium chloride with a conc. *potassium amalgam*, and distilled the mercury from the resulting amalgam in vacuo. F. Wöhler failed to verify H. C. Oersted's results, but obtained aluminium in the form of a grey powder by warming a mixture of potassium and aluminium chlorides contained in a porcelain crucible. J. von Liebig passed the vapour of aluminium chloride over *potassium*, and this plan was later employed by F. Wöhler. H. St. C. Deville reduced aluminium chloride with *sodium*, and he found that the reaction is facilitated by the presence of cryolite which serves as a flux, forming a slag light enough to allow the aluminium to collect below. The industrial success of the process depended on the cheap production of large quantities of sodium; the production of purified alumina; and the conversion of the aluminium oxide into chloride.

In H. St. C. Deville's process, a mixture of 220 lbs. of aluminium chloride, 100 lbs. of cryolite, and 77 lbs. of sodium was charged into a reverberatory furnace, with a well, and a sloping hearth, and at a dull red-heat. The temp. was regularly increased for about 3 hrs. The slag was first tapped, then the aluminium, and finally a mixture of sodium chloride and cryolite containing beads of aluminium was tapped last. In 1872, A. Wurtz estimated the costs of materials, fuel, wages, and other expenses to be 70·25–80·00 francs per kilogram of aluminium.

H. Rose obtained aluminium by heating in a crucible a mixture of 5 parts of cryolite, 5 parts of potassium chloride, and 2 parts of sodium. A similar process involving the reduction of cryolite by sodium was described by A. Dick, C. Brunner, M. Herzog, L. Grabau, W. F. Gerhard, J. B. Thompson and W. White, M. Ichon, W. Weldon, J. Webster, A. Stevart, M. Rousseau and P. Morin, B. Kosmann, W. Anderson, etc.

A. Dick lined a platinum crucible with magnesia, and introduced alternate layers of cryolite and sodium, finishing with a thick layer of cryolite. The crucible was closed with a tight-fitting lid, and heated in the blowpipe flame. There resulted some globules of aluminium. Iron, porcelain, and fireclay crucibles were not satisfactory; in the first case, the aluminium "seemed to alloy with the sides of the crucibles, which thereby acquired a colour like zinc"; in the other cases, the fluorides attacked the crucibles vigorously.

M. A. Brogowsky passed the vapour of sodium over the molten cryolite. H. Rose's process was employed for a time by C. and A. Tissier at Amfreville. N. V. Castner improved the method of making sodium, and used sodium aluminium chloride mixed with cryolite. The process was employed near Birmingham about 1899. C. Netto reduced artificial cryolite by sodium by H. Rose's old process, and it was used for a time by The Alliance Aluminium Co., at Wallsend-on-Tyne. L. Grabau reduced aluminium fluoride with sodium: $2AlF_3+3Na=Al+AlF_3.3NaF$, and recovered the fluoride by treatment with aluminium sulphate: $Al_2(SO_4)_3+2Na_3AlF_6=4AlF_3+3Na_2SO_4$. A. Feldmann heated a mixture of strontium aluminium fluoride with sodium: $Al_2F_6.3SrF_2+6Na=2Al+3SrF_2+6NaF$. The strontium fluoride is insoluble in water so that the other materials can be washed away, and the strontium fluoride used for making more double fluoride. H. St. C. Deville tried to produce the sodium and aluminium in one operation by passing the vapour from a heated mixture of lime, carbon, and soda into heated aluminium chloride; W. Frishmuth likewise allowed the vapours of aluminium sodium chloride and of sodium to react in a suitable receptacle. H. D. Gadsden, H. Foote, H. Niewerth, and L. Henne used modifications of the process.

From their study of the direct reduction of alumina by *carbon*, R. S. Hutton and J. E. Petavel[3] inferred (1) that metallic aluminium can be produced by a purely thermal reaction; (2) that the lowest temp. at which this reaction can take place coincides with the m.p. of alumina; (3) that the metal is first produced in the form of vapour. Under ordinary circumstances, however, the metal vapour immediately interacts with the carbon monoxide, and to collect the pure metal it is therefore necessary (1) to dilute and remove the carbon monoxide, (2) to limit the vaporization of the metal by working under high gaseous press. In this way it has been possible to prepare and collect 40–50 grms. of aluminium. P. Askenasy and N. Lebedeff found that a mixture of alumina and wood charcoal heated in an arc furnace at first gives off large quantities of carbon monoxide followed by brilliant flames of burning aluminium vapour. If the heating be stopped as soon as these appear, the product consists of fused alumina mixed with aluminium carbide and aluminium. In the carbon tube resistance furnace, where the highest temp. reached is not much above the m.p. of alumina, both carbide and metal were formed. It is thought that aluminium carbide is first formed, $2Al_2O_3+9C=Al_4C_3+6CO$, and that this reacts with alumina, or dissociates at a higher temp. yielding aluminium which is probably dissolved by the carbide, otherwise it would distil away; on cooling, the aluminium separates from the soln., and is found side by side with the carbide in the cold product. L. Burgess heated a mixture of bauxite and carbonaceous matter in the electric arc. According to the purity of the material and the proportion of carbon, the product may be aluminium, the carbide, or mixture of either with other carbides or metals.

W. F. Gerhard claimed to have obtained aluminium by heating aluminium fluoride or cryolite to redness in a stream of *hydrogen*. A. Schneller and A. Astfalck claimed to have obtained aluminium by heating the oxide, fluoride, or chloride to the temp. of the electric arc in a stream of hydrogen; and H. N. Warren passed hydrogen over alumina in a tube of lime heated by the oxyhydrogen blowpipe flame. L. P. B. E. Cumenge reduced aluminium sulphide with hydrogen. A. L. Fleury heated an intimate mixture of alumina and carbon—tar, resin, petroleum—to redness in an atm. of a *hydrocarbon* gas under a press. of 20–30 lbs. per sq. in. H. Bessemer proposed reducing a mixture of alumina and carbon by burning gases under 3–4 atm. press. T. L. Willson heated a mixture of alumina and tar in an electric furnace. J. S. Howard, F. G. Bates, and F. P. Pendleton heated a mixture of alumina, carbon, and sodium chloride; E. Meyer heated a mixture of alkali aluminate and carbon, sawdust, or carbohydrate. Various modifications of the process for reducing aluminium sulphide with hydrocarbons or carbon have been suggested by D. A. Peniakoff, H. F. D. Schwahn, D. G. Reillon and co-workers, G. A. Faurie, W. Rübel, etc. D. G. Reillon, S. C. Montagne, and O. L. B. L. Bourgerel, and T. Petitjean reduced aluminium sulphide, or sodium aluminium sulphide, with hydrocarbon gases. N. Lebedeff fluxed alumina with fluorspar or cryolite, and exposed the molten mass to hydrogen or hydrocarbon gas. J. W. Richards' experiments in this direction were fruitless. In 1854, M. Chapelle claimed to have obtained globules of metal from an intimate mixture of natural clay, sodium chloride, and carbon contained in a fireclay crucible heated in a reverberatory furnace with coke as fuel. J. W. Richards has suggested that M. Chapelle's metallic globules were siliceous iron reduced from the iron oxide in the clay. W. Hempel expressed his doubts whether alumina can be reduced by carbon in a purely thermal reaction. H. Moissan, and W. Borchers noted the formation of aluminium carbide and aluminium at high temp., and the former assumed that it is the vapour of alumina which is reduced by carbon. E. Tiede and E. Birnbräuer give 1800° for the reduction temp. of alumina by carbon. O. Knöfler and H. Ledderboge made a mixture of alumina and carbon into rods which were used as electrodes for an electric arc in vacuo or in an atm. of an indifferent gas. J. M. A. Gérard-Léscuyer used a somewhat similar process. E. Duvivier reduced disthene between carbon electrodes in the electric arc furnace. G. W. Reiner stated that the mass obtained by heating a mixture of soda or potash alum with carbon contains an alloy of aluminium and the alkali metal, and that the latter can be removed by dil. nitric acid. W. A. Baldwin heated a mixture of bauxite, carbon, and sodium chloride, and then melted the resulting sodium-aluminium alloy with sodium chloride to separate the aluminium. N. Lebedeff reduced the sulphide with carbon. O. M. Thowless obtained aluminium by heating a mixture of aluminium chloride, chalk, coal, soda, and cryolite in a closed vessel; S. Pearson, J. Liddon, and J. H. Pratt likewise heated a mixture of cryolite, bauxite or clay, calcium chloride or carbonate, and coke or anthracite. R. E. Green heated a mixture of aluminium fluoride or cryolite with carbon and a silicate, contained in a carbon crucible in an atm. of coal gas: $AlF_3.3NaF+SiO_2+2H_2=Al+Na+Na_2SiF_6+2H_2O$. S. Pearson, A. W. Turner, and W. Andrews claimed to have made aluminium by heating aluminium silicate with calcium fluoride, and an alkali carbonate or hydroxide. D. G. Reillon, S. C. Montagne, and O. L. B. L. Bougerel heated a mixture of clay and carbon in an atm. of a hydrocarbon and *carbon disulphide*. G. A. Faurie heated a mixture of sulphur, clay, and carbon to redness; carbon disulphide is first formed, and finally aluminium. J. Morris claimed to have obtained aluminium by heating an intimate mixture of alumina and charcoal in an atm. of carbon dioxide. S. A. Tucker and H. R. Moody reduced alumina with *calcium carbide* in an electric furnace: $CaC_2+Al_2O_3=2Al+2CO+CaO$; and H. S. Blackmore, and P. R. Hershman, with *aluminium carbide*, $Al_2O_3+Al_4C_3=6Al+3CO$. E. Straub described a process involving the reduction of alumina with aluminium carbide.

F. C. Knowles proposed to reduce a mixture of alumina and aluminium chloride with *potassium or sodium cyanide*; I. L. Bell tried a similar process but obtained no metal. L. F. Corbelli heated a mixture of aluminium sulphate with sodium chloride and *potassium ferrocyanide* in a crucible to a white heat. H. St. C. Deville obtained no satisfaction with this process, and the button of metal probably consisted chiefly of iron.

L. P. B. E. Cumenge[4] heated aluminium sulphide with alumina or aluminium sulphate in a non-oxidizing atm. The proportions employed are such as to produce only aluminium and sulphur dioxide: $Al_2S_3+2Al_2O_3=6Al+3SO_2$; and $Al_2S_3+Al_2(SO_4)_3=4Al+6SO_2$. It is also claimed that aluminium sulphate can be used with other metal sulphides to produce alloys: $Al_2(SO_4)_3+3FeS=6SO_2+2Al.3Fe$. J. Malovich applied his process for barium to aluminium. G. Gin described a process in which a molten mixture of aluminium and sodium sulphides formed by melting together aluminium fluoride and sodium sulphide: $6Na_2S+4AlF_3$

$=2(AlF_3.3NaF)+3Na_2S.Al_2S_3$, was electrolyzed. In the first stage of the reaction $3Na_2S.Al_2S_3=3Na_2S+3S+2Al$, and the liberated sodium sulphide attacks the double fluoride, forming more double sulphide; finally, $3Na_2S+2(AlF_3.3NaF)=12NaF+3S+2Al$. T. Petitjean, and M. Herzog suggested reducing aluminium sulphide with *iron* or hydrocarbons. F. Lauterborn said that aluminium sulphide is reduced by iron at a red heat. W. A. Baldwin, G. Bamberg, G. H. Billings, L. Q. Brin, F. C. Calvert and R. Johnson, A. Chenot, E. Cleaver, J. H. H. Corbin, L. P. B. E. Cumenge, M. Faraday and J. Stodart, M. Grüner and M. Lan, C. T. Holbrook, A. Ledebur, M. Lohage, A. Mann, H. Niewerth, P. Ostberg, S. Pearson and J. H. Pratt, F. G. Reichel, C. E. Schafhäutl, J. A. Stephan and R. Southerton, W. P. Thompson, etc., have dealt with the production of iron-aluminium alloys.

L. P. Devaucelle made an alloy of *zinc* or *copper* by heating aluminium sulphide with an excess of one of these metals. A. Mann reduced aluminium sulphide with zinc, iron, or copper: $2AlCl_3+Al_2S_3+3CaCl_2+6Cu=6CuCl_2+3CaS+4Al$. E. L. Benzon, P. Bolley, L. Q. Brin, F. C. Calvert and R. Johnson, L. P. B. E. Cumenge, G. A. Faurie, W. Hampe, K. List, F. G. Reichel, etc., have studied the reduction of aluminium compounds with copper, and the production of aluminium-copper alloys. N. N. Beketoff could not reduce the vapour of aluminium chloride by the vapour of zinc, although silicon chloride is readily reduced. H. St. C. Deville said that a mixture of zinc and sodium aluminium chloride detonated at a white heat. M. Dullo found the reduction by zinc presents no difficulty, although it is less easy than with sodium, and N. Basset stated that "all the metalloids and metals which form, by decomposition, more fusible or more soluble chlorides than aluminium chloride may reduce it or even sodium aluminium chloride. Thus, arsenic, bismuth, copper, zinc, antimony, mercury, or even tin, or an amalgam of zinc, tin, or antimony may be employed to reduce the single or double chloride." F. Flavitzky found that zinc is quantitatively displaced by aluminium from zinc chloride. The reaction is probably reversible. The process has been discussed by H. Wedding. Processes for reducing aluminium salts by zinc have been devised by F. J. Seymour, L. P. Devaucelle, L. P. B. E. Cumenge, F. Lauterborn, A. Mann, J. Clark, G. Bamberg, S. van Oldruttenborgh, R. de Montgelas, etc. A. J. Rogers said that the molten cryolite is reduced by an alloy of sodium with *lead* or *tin* more easily than by sodium alone; and A. E. Wilde obtained aluminium by heating an intimate mixture of lead or lead sulphide and dried alum. The Aluminium Product Co. reduced aluminium chloride with tin. W. Weldon claimed to produce aluminium by heating the chloride or sulphide with *manganese* or spiegeleisen and adding a little sodium to promote the reaction. W. H. Greene and W. H. Wahl noted the converse reaction, for manganese is obtained by the action of aluminium on a soln. of manganese oxide in molten cryolite. N. N. Beketoff said that *magnesium* reduces molten cryolite; C. Winkler obtained what he regarded as a suboxide, AlO, by the action of powdered magnesium on heated alumina in an atm. of hydrogen. R. Grätzel reduced alkali aluminium fluoride by metallic magnesium or magnesium vapour, and R. de Montgelas reduced aluminium chloride with magnesium. B. Kosmann reduced cryolite with magnesium, or in the presence of magnesium chloride undergoing electrolysis. F. Lauterborn heated a mixture of *antimony*, sodium carbonate, and aluminium sulphate in a coke furnace. In the first stage of the reaction: $2Sb_2S_3+6Na_2CO_3+3C=6Na_2S+9CO_2+4Sb$; and in the second stage: $2Al_2(SO_4)_3+6Na_2S+4Sb+12C=4Na_3SbS_3+12CO+4Al$. F. Fischer added that these extraordinary formulæ have little or no basis in chemical science; they are false. J. W. Richards obtained negative results. L. Grabau was not very successful in an attempt to reduce aluminium salts with *phosphorus*, although he did get an aluminium-phosphorus alloy. M. Wanner suggested reducing molten aluminium fluoride with the extraordinary reagent *silicon sulphide*.

The electro-deposition of aluminium from aqueous solutions of its salts.—Z. Roussin [5] said that magnesium does not precipitate metallic aluminium from soln. of its salts, but J. W. Richards added that aluminium is so precipitated but instantly oxidized by the water; thus S. Kern found that aluminium hydroxide appears when magnesium is immersed in aq. soln. of aluminium salts. F. Wöhler could get no aluminium by the electrolysis of a soln. of cryolite in an aq. soln. of sodium hydroxide; nor did H. St. C. Deville obtain any metal by the electrolysis of aq. soln. of aluminium salts. On the other hand, F. S. Thomas and W. E. Tilley electrolyzed a soln. of freshly precipitated alumina or alum in a soln. of potassium cyanide, and claimed to have deposited aluminium; and L. F. Corbelli said that he deposited aluminium by electrolyzing a mixed soln. of alum or aluminium sulphate and calcium or sodium chloride; G. Gore said that he electro-deposited aluminium on copper from a warm dil. soln. of aluminium hydroxide in hydrochloric acid; from a sat., aq. soln. of potash alum; from a conc. soln. of aluminium acetate; and from a cold, filtered soln. of pipeclay in hydrochloric acid. A. Bertrand electro-deposited aluminium on a copper plate from a soln. of ammonium aluminium chloride; T. Ball used a soln. of potassium aluminium chloride; and patents have been obtained by J. Braun, L. and A. Brin, H. C. Bull, C. A. Burghardt and W. J. Twining, S. Coulson, R. A. Falk and A. Schaag, M. G. Farmer, W. Frishmuth, W. F. Gerhard and J. Smith, A. F. B. Gomess, A. H. Harris, J. S. Haurd, J. A. Jeançon, J. Marino, R. de Montgelas, G. Nahnsen and J. Pfleger, G. von Overbeck and H. Niewerth, M. Rietz and M. Herold, A. J. Rogers, L. Senet, A. Walker, H. N. Warren, S. Wohle, etc. Several of these processes have been challenged by F. Wöhler, and H. St. C. Deville. J. Nicklès said that in some cases the precipitated metal is not aluminium; F. Fischer showed that J. Braun mistook a deposit of cupric sulphide for aluminium. G. Gore, also, in his later work, makes allusion to his 1854 process. S. Mierzinsky claimed that in 1883, the electro-deposition of aluminium from aq. soln. had not been accomplished; and W. Hampe, A. Watt, C. Winkler, and J. T. Sprague have recorded their failure to deposit aluminium electrolytically in the wet way. W. A. Plotnikoff found that aluminium is deposited on the carbon cathode when a soln. of aluminium bromide in ethyl bromide is electrolyzed; H. E. Patten confirmed this result, using platinum as well as aluminium electrodes.

The electro-deposition of aluminium from molten aluminium salts.—In 1808, H. Davy [6] applied his method of decomposing the alkali hydroxides to alumina, but, owing to the weakness of the available current, he obtained no aluminium; in 1810, however, he did succeed in producing an alloy of aluminium and iron by fusing iron to whiteness in the arc in contact with alumina. He thus showed that alumina can be decomposed in the electric arc, and its metal alloyed with iron. R. Bunsen first obtained aluminium by the electrolysis of fused sodium aluminium chloride, contained in a partitioned, porcelain crucible using carbon electrodes, and similar to the apparatus which he employed for magnesium. At low temp., the aluminium was obtained as a grey powder, but by working at a higher temp., with sodium chloride also present, beads of the metal were obtained. H. St. C. Deville decomposed fused sodium aluminium chloride by electrolysis about the same time as R. Bunsen. He used the apparatus illustrated by Fig. 1. A porcelain crucible, *D*, is fitted inside a fireclay crucible *E*. The fireclay cover *B* has apertures to admit a strip of platinum *K* to serve as cathode; and a porous cell *C* containing a carbon anode *A*. The porcelain crucible and porous cell are filled to the same level with fused sodium aluminium chloride, and the current is passed. Aluminium deposits on the cathode. H. St. C. Deville used a similar bath for plating metals, particularly copper. He said:

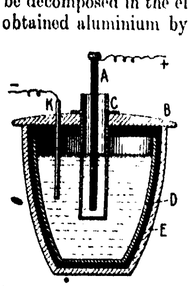

FIG. 1.—H. St. C. Deville's Cell for the Electrolysis of Sodium Aluminium Chloride.

> A bath of double chloride, which has been entirely purified from foreign metallic matter by the action of the battery itself, is used. When aluminium is being deposited at the negative pole, the first portions of metal obtained are always brittle, the impurities in the bath being

removed in the first metal thrown down; so, when the metal deposited appears pure, the piece of copper to be plated is attached to this pole and a bar of pure aluminium to the positive pole. However, a compact mixture of carbon and alumina can be used instead of the aluminium anode, which acts similarly to it and keeps the composition of the bath constant. The temp. ought to be kept a little lower than the fusing point of aluminium. The deposit takes place readily and is very adherent, but it is difficult to prevent it being impregnated with double chloride, which attacks it the moment the piece is washed. The washing ought to be done in a large quantity of water. Cryolite might equally as well be used for this operation, but its fusibility should be increased by mixing with it a little double chloride of aluminium and sodium and some potassium chloride.

H. le Chatelier patented a very similar process, using a mixture of alumina and carbon for the anode, as recommended by H. St. C. Deville. M. G. Farmer used the containing vessel with walls electrically conducting so as to serve as cathode. J. P. Kagensbusch electrolyzed a fused mixture of clay with fluxes and zinc or like metal so as to obtain an alloy of aluminium. H. M. A. Berthaut electrolyzed a fused mixture of equal parts of cryolite and sodium chloride. A. Feldmann obtained better results by adding a little calcium oxide to the electrolyte. The electrolysis of molten cryolite has been studied by E. C. Kleinert, A. J. Rogers, A. Zdziarsky, I. Omholt, J. W. Richards, M. Gauduin, J. Garneri, C. A. Faure, etc. W. Diehl showed that in the presence of alkali chloride, chlorine is evolved at the anode, and the spent electrolyte can be reconverted into a double aluminium fluoride by adding alum: $7NaF+2KAl(SO_4)_2=NaF.2AlF_3+K_2SO_4+3Na_2SO_4$. A. Minet electrolyzed a mixture of sodium chloride with 37·5 per cent. of cryolite fused internally. The bath was replenished from time to time by the addition of aluminium fluoride. The method has been discussed by W. Borchers; and the electrolysis of a fused mixture of cryolite and alkali chloride by W. Hampe, and O. Schmidt. Modifications of the process have been described by L. Grabau, M. J. Berg, L. Lossier, R. Grätzel, H. de Grousilliers, F. J. Tone, F. Haber and R. Geipert, M. Sprenger, F. A. Gooch and L. Waldo, J. L. E. Daniel, etc. A. Feldmann used double fluorides of aluminium and the alkaline earths, magnesium, or zinc in place of alkali aluminium fluoride.

A. H. Bucherer,[7] electrolyzed the product obtained by melting a sulphide or polysulphide of the alkalies or alkaline earths with alumina or aluminium hydroxide; and M. M. Jännigen electrolyzed the double sulphide obtained by passing carbon disulphide over a molten mixture of alumina and alkali carbonate. A. Winkler electrolyzed fused aluminium phosphate or borate. A. Julien proposed to electrolyze a soln. of alumina in fused sodium chloride, fluorspar, alkali silicate, sodium borate, or boric acid; and M. Blasi, a bath of a soln. of alumina in fused baryta.

The electro-deposition of aluminium from a solution of alumina in fused cryolite.—In 1886, P. L. V. Héroult[8] obtained aluminium by the electrolysis of a soln. of alumina in fused cryolite contained in a crucible heated from without. Attempts to manufacture aluminium by the electrolysis of a bath of the fused halide, externally heated have not been successful. It is difficult to procure a suitable containing vessel to resist the corrosive action. If the crucibles contain silica, then the deposited metal is contaminated with silicon derived from the silica dissolved from the containing vessel. Compressed coke crucibles are too porous; metal vessels do not stand against the corrosive action. This difficulty was overcome by generating the necessary heat for fusing the electrolyte within the containing vessel. The same year, C. M. Hall likewise proposed to electrolyze a soln. of alumina in fused cryolite. For the purposes of the American patent, C. M. Hall was able to cite Feb. 23, 1886, as the date of the invention and putting into practice, while P. L. V. Héroult cited April 23, 1886, as the date of his French invention. As a result, C. M. Hall received the American patent on April 2, 1889. He claimed:

Dissolving alumina in a fused bath composed of the fluorides of aluminium and a metal more electropositive than aluminium, and then passing an electric current through the fused mass. Dissolving alumina in a fused bath composed of the fluorides of aluminium and sodium and then passing an electric current, by means of a carbonaceous anode, through the fused mass.

The losses in fluorine are made good by additions of aluminium fluoride; and fresh alumina is added to the bath, to make up for that which has been reduced to aluminium. The later forms of the two processes are the same in principle. In both processes, the current not only performs the work of electrolysis, but also melts the electrolyte, and continually makes good the losses of heat due to radiation and conduction. There are modifications in the composition of the bath, and in the form of the cells, in different works. Furnaces have been devised by L. Grabau, B. Neumann and H. Olsen, M. Schindler, E. C. Kleinert, L. Lossier, R. J. Henderson, etc., and the subject has been discussed by J. W. Richards, M. Kuss, B. Kosmann, R. J. Henderson, W. Borchers, A. Lodin, etc. In general, the baths are made of wrought-iron, and the walls are coated with solid electrolyte which protects the iron from corrosion by the melted electrolyte. Some baths have a carbon lining but it is then difficult to prevent the molten electrolyte working its way through the capillary pores. The bottom of the bath is covered with carbon plates, Fig. 2, which serve as cathode until they are covered with aluminium, when the metal itself acts as cathode.

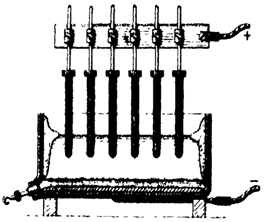

Fig. 2.—Cell for the Electrolysis of a Solution of Alumina in Fused Cryolite (Diagrammatic).

The leads of the anode are screwed on an insulated support so that they can be lowered as they are burnt by the anodic oxygen, and as the resistance of the bath varies. Air circulates about the bath so that a crust of electrolyte freezes on the surface inside. A tapping hole allows the aluminium to be run into moulds from time to time. Water-cooled cathodes have been tried; but the objection is the attack of the metal by the electrolyte, thus introducing impurities into the bath. The carbon anodes are costly, since almost three-fourths as much carbon is consumed by anodic oxygen as aluminium is produced—approximately $Al_2O_3+3C=3CO+2Al$. The anodes are also burnt by atm. oxygen. The anodes must contain very little impurities other than alumina, or the bath, and subsequently the aluminium, will be contaminated. The manufacture of the anodes has been described by W. Clacher; and the best form of anode has been investigated by F. Bock.

G. H. Bailey and R. Seligman have shown that the consumption of carbon, in practice, is much less than is represented by $Al_2O_3+3C=3CO+2Al$, assumed by J. W. Richards, F. Haber, etc., to represent the main reaction. According to G. H. Bailey, the composition of the anode gases corresponds more nearly with $2Al_2O_3+3C=4Al+3CO_2$. With normal anode consumption, the temp. of the bath being 945°, R. Seligman found the anode gases to contain CO_2, 45·6; CO, 43·6; O_2, 0·8; and N_2, 10 per cent. The nitrogen present does not account for the presence of carbon dioxide as burnt carbon monoxide. It is therefore assumed that the alumina itself is electrolyzed so that the aluminium is liberated at the cathode and oxygen at the anode, and the oxygen then unites with carbon to form carbon monoxide and carbon dioxide. Some of the carbon monoxide burns to carbon dioxide in contact with air. The composition of the anode gases is therefore dependent upon temp., current density, physical character of anode, rapidity with which the gases are removed from contact with the anode, etc. A. Minet suggested that the aluminium liberated at the cathode is really produced by the decomposition of the aluminium fluoride, and that the fluorine liberated at the anode attacks the alumina, reforming fluoride and liberating oxygen: $Al_3O_1+F=Al_1F+O_1$- but this hypothesis has been abandoned.

Alumina alone melts at so high a temp. that a solvent must be obtained. Cryolite melts a little below 1000°. The fusibility of the cryolite is lowered by the addition of other fluorides—aluminium fluoride, or calcium fluoride. F. Haber says that the temp. of the bath should be kept as low as practicable, fluctuating between 900° and

1000°, but never exceeding 1065° ; J. W. Richards gave 900°–950° for the bath temp. The effect of fluorspar on the m.p. of cryolite as found by P. Pascal and A. Jouniaux is shown in Fig. 3; there is a eutectic at 905° containing 25·4 per cent. of fluorspar. Mixed crystals are formed with 20·5 and 50 per cent. of fluorspar. The effect of calcium fluoride on the m.p. of cryolite has been determined by P. P. Fedotieff and W. Ijinsky, and by N. A. Puschin and A. Baskoff, Fig. 6. P. Pascal and A. Jouniaux found that alumina lowers the m.p. of cryolite from 977° to the eutectic at 904° with 24 per cent. of alumina—Fig. 4. Mixed crystals occur with 20 and 29 per cent. of alumina. R. Lorenz and co-workers place the eutectic at 937°–938° with 32–33 molar per cent. of alumina ; and M. Moldenhauer, at 880° with 20 per cent. alumina. Similarly, P. Pascal and A. Jouniaux state that alumina lowers the m.p. of fluorspar from 1361° to the eutectic at 1270° with 26·5 per cent. of alumina—Fig. 5. Mixed crystals with 20 and 28·5 per cent. of alumina are formed. P. Pascal and A. Jouniaux studied the m.p. of the ternary system containing cryolite, alumina, and fluorspar. The liquidus system is shown in Fig. 6, and the solidus system in Fig. 7 ; the contour lines are drawn for each 50° difference of temp. The eutectic in Fig. 6 at 868° has 59·3, 23·0, and 17·7 per cent. respectively of cryolite, fluorspar, and alumina. The mixed crystals composing the ternary eutectic in Fig. 7 contain the percentage amounts cryolite, fluorspar, alumina as 77 : 16 : 7 ; 60 : 15 : 25 ; and 34 : 54 : 12.

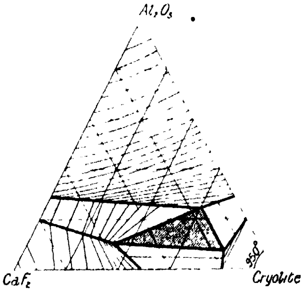

Fig. 7.—Solidus of the Ternary System: Cryolite, Fluorspar, Alumina.

J. W. Richards found the sp. gr. of solid and liquid commercial aluminium to be 2·66, and 2·54; of commercial cryolite, 2·92 and 2·08; of commercial cryolite sat. with alumina, 2·90 and 2·35; of commercial cryolite with aluminium fluoride $3NaF.AlF_3+2AlF_3$, 2·96 and 1·97; and of the same mixture sat. with alumina, 2·98 and 2·14. The sp. gr. of cryolite at ordinary temp. is greater than that of aluminium, so that if this condition were maintained at the temp. of the bath, the metal would float on the molten flux. At the temp. of elctrolysis, however, the sp. gr. of the metal is the greater, and it accordingly collects at the bottom of the cell. P. Pascal and A. Jouniaux's data are:

	658°	682°	740°	802°	868°	925°	1000°
Sp. gr. Al . .	2·46	2·45	2·43	2·41	2·39	2·37	2·35

Molten cryolite has a point of maximum density at 995°, when the sp. gr. is 2·22. Thus,

	972°	978°	995°	1003°	1032°	1061°	1083°
Sp. gr. cryolite .	2·185	2·203	2·220	2·209	2·189	2·154	2·102

The sp. gr. of cryolite is decreased by the addition of silica, and increased by the addition of fluorspar; the sp. gr. of ternary mixtures of cryolite, fluorspar, and alumina are shown graphically in Fig. 8. K. Arndt and W. Kalass have investigated the conductivity of soln. of alumina in molten cryolite.

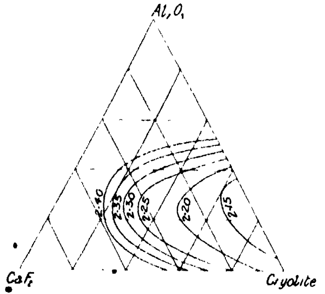

FIG. 8.—Specific Gravities of Ternary Mixtures of Cryolite, Fluorspar, and Alumina at 950°

J. W. Richards said that the sp. resistance of the electrolyte is 3 ohms per c.c., and estimated the decomposition voltages of the constituents of the bath to be approximately 4·7 volts for sodium fluoride, 4·0 volts for aluminium fluoride, and 2·2 volts for alumina. Assuming that these values are correct, alumina will decompose first. If high current densities be used, sodium will be liberated, and fluorine may be liberated at the anode if the proportion of alumina in the bath be very low, or the current density be high. There are so many difficulties in preventing the baths from clogging, becoming discoloured, and ceasing to operate properly that the production of aluminium by electrolysis on a laboratory scale is difficult. One difficulty is due to polarization at the anode owing to the formation of a film of gas, which reduces the current so much that the bath freezes. If a higher voltage be used, the bath is heated locally, and the aluminium is oxidized. This is prevented to some extent by using an anode with a large surface area. The production of aluminium on a small scale has been studied by F. Haber and R. Geipert, M. de K. Thompson, B. Neumann and H. Olsen, N. A. Puschin, E. Dischler and M. Maksimenko, H. K. Richardson, etc. The current consumed by the cell is approximately 10,000 amps. at 5·5 volts, and the current density at the cathode is 100 amps. per sq. dm., and about 500 amps. per sq. dm. at the anode. For the plant examined by F. Haber the current efficiency was 71 per cent.; the voltage, 5·5; the current, 7520 amps.; the yield of metal, 43·1 kgrms. per 24 hrs.; and the energy consumption 23,000 kilowatt hours per ton. The chief losses are due to the formation of a metal fog which diffuses from cathode to anode, resulting in a regeneration of alumina at the anode; there are also losses due to short circuiting between anode and cathode.

Electro-thermal processes for aluminium alloys.—The brothers E. H. and

A. H. Cowles[9] showed that if alumina be heated with carbon and a metal oxide, an alloy of aluminium with the metal is obtained—*e.g.* cupro-aluminium. Several modifications of the furnace were proposed. The mixture is heated by passing a current through the mixture *A*, Fig. 9, to be heated *viâ* carbon electrodes *C*, *C*. The reaction is thermic not electrolytic, for, said B. Kosmann, the electric current is utilized by its conversion into heat by the resistance offered; pure electroylsis is either absent, or occurs to so small an extent as to be inappreciable. W. Borchers has described a number of these resistance furnaces. That shown in Fig. 10 has two carbon rods *A*, *A* fitted with a thin carbon pencil *B* between them. This lies in the axis of a paper cartridge filled with the mixture to be heated—say clay, carbon, and copper oxide. This is covered over with coarse carbon powder. The circuit *CC* is closed, and in a few minutes a copper aluminium alloy is formed. E. Viel made ferro-aluminium alloys by a somewhat similar process. J. H. J. Dagger, W. P. Thompson, C. F. Mabery, and T. S. Hunt have described E. H. and A. H. Cowles' processes for making aluminium alloys.

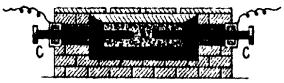

Fig. 9.—A. H. and E. H. Cowles' Resistance Furnace.

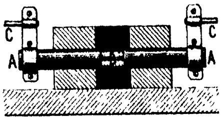

Fig. 10.—W. Borcher's Resistance Furnace

The impurities in commercial aluminium.—A. Salvetat[10] analyzed Deville's aluminium in 1856, and found that it contained copper, iron, silicon, and traces of lead as impurities. J. W. Mallet found traces of sodium and titanium. O. L. Erdmann found zinc to be present. In 1868, C. F. Rammelsberg reported 0·7 per cent. of silicon and 4·6 7·5 per cent. of iron in a sample of commercial aluminium; and in 1876, W. Hampe found 0·4 to 1·0 per cent. of silicon, 1·3 to 1·4 per cent. of iron, 0·2 per cent. of lead, 0·1 to 0·4 per cent. of copper. Analyses of the metal prepared by the sodium process have also been given by C. H. Hirzel, C. Karmarsch, etc. H. Moissan found that electrolytic aluminium contained iron and silicon, 0·1 per cent. of carbon, and some nitrogen. Numerous analyses of modern aluminium have been published, since it is the fashion to give the analysis of the material used in description of the physical and chemical properties of the metal. First-grade aluminium contains 99 per cent. or more aluminium, and the second-grade metal 98 to 99 per cent. aluminium. The chief impurities are iron and silicon. Thus G. H. Bailey quotes analyses of 18 samples with 95·48 to 99·65 per cent. aluminium; 0·029 to 3·22 per cent. of iron; and 0·17 to 0·64 per cent. of silicon. Two of the samples had 0·09 to 0·116 per cent. of sodium; and four samples 0·30 to 3·70 per cent. of copper. R. Seligman and P. Williams quotes five samples with 0·14 to 1·3 per cent. of iron; 0·13 to 1·4 per cent. of silicon; and in one sample there was 0·3 per cent. of copper. R. L. y Gamboa, and C. Boulanger and J. Bardet found gallium in specimens of aluminium and of bauxite. J. Czochralsky found traces of aluminium oxide, and carbide in the commercial metal. Virtually no sodium, aluminium sulphide or phosphide was present.

The purification of aluminium.—H. St. C. Deville found that ferruginous aluminium can be partially purified by a kind of liquation. To free the metal from sodium and slag, the molten metal was kept fused in contact with air for a long time and the surface film was skimmed off. Fusion under potassium polysulphide partially removes some lead, copper, and iron. He obtained the best results by fusing the metal with nitre in a cast-iron crucible well oxidized itself by nitre on the inside. W. Diehl claimed to remove iron by fusion with sulphur; P. E. Placet used potassium dichromate and permanganate; and U. J. J. le Verrier said that he reduced the silicon in a sample of aluminium from 0·81 to 0·57 per cent. by fusing the metal under a layer of alkali fluoride. A. G. Betts, and The Pittsburg Reduction Co. tried electrolytic methods of purification. H. St. C. Deville, and C. and A. Tissier cleaned the surface of aluminium by washing it first with an aq. soln. of potassium hydroxide, and then with nitric acid *vide* etching aluminium. J. W. Mallet in his *Revision of the atomic weight of aluminium* (1880) started with commercial aluminium containing 96·89 per cent. of aluminium, 1·84 per cent. of iron, and 1·27 per cent. of silicon. This was treated with liquid bromine, and the resulting aluminium bromide purified by fractional distillation repeated until the product was perfectly colourless, and dissolved in water without leaving any perceptible impurity. The bromide was reduced by treating it in a crucible made of a mixture of alumina and sodium aluminate. On analysis, the metal gave no weighable impurities. E. Strasser treated the molten metal with the vapour from nitric acid. F. and W. Mylius purified aluminium by fractional freezing of the molten metal; the first portions to crystallize are the purest.

O. Ohmann[11] prepared *aluminium wool*. J. Billitzer, F. Ehrenhaft, T. Svedberg, and D. Zavrieff made **colloidal aluminium.** The last-named failed with G. Bredig's process (**2.** 23, 10), but he succeeded by placing two electrodes of aluminium 0·1 mm. apart in a vessel of water, and passing a current from an induction coil fed by 15–20 amps. at 120 volts, and having a spark 20 cms. long—the coil was in circuit with a large condenser. The colloidal soln. could be kept nearly a month without flocculation. C. H. Hall studied the electrical precipitation of finely divided aluminium

§ 4. The Physical Properties of Aluminium

F. Wöhler,[1] and J. W. Mallet likened the **colour** of compact aluminium to that of tin. C. Karmarsch said that the colour of commercial aluminium resembles that of platinum and comes between that of zinc and of tin; and H. St. C. Deville, that the colour has rather a bluer tinge than silver. J. W. Richards says that aluminium has a blue tinge after it has been worked or polished. The blue is also more pronounced the greater the amount of impurity the metal contains. A specimen with 10 per cent. of silicon and 5 per cent. of iron was almost as blue as lead. The metal prepared by F. Wöhler's process appears as a dull grey powder which acquires a metallic lustre when rubbed with a burnishing tool. M. Faraday obtained films of aluminium by deflagrating the metal by the Leyden battery and catching the vapour on glass plates. In reflected light the film is white and metallic; in transmitted light it is dark brown, bluish-brown, and occasionally, in the thinner parts, orange, A. W. Wright heated aluminium foil in an evacuated tube, by means of an electric discharge, and obtained a mirror of sublimed metal which appeared brown in transmitted light; J. A. Fleming likewise obtained a blue film. Very thin aluminium-leaf is violet-blue in transmitted light. According to H. Moissan, the vapour of aluminium is greyish-blue; and, according to W. L. Dudley, greenish-blue. According to J. W. Richards, purified aluminium has no odour, but the metal with over one per cent. of silicon exhales the odour of silicon hydride, and similar to that which proceeds from cast-iron. The smell of second-grade aluminium is best detected immediately after a brisk rubbing; purified metal has no taste, but the impure metal seems to taste like cast-iron.

No allotropic form of aluminium has been observed. Aluminium, said J. W. Mallet, has a crystalline fracture, and that of the cast ingot being slightly fibrous. Mechanical work makes the fracture more fibrous; and, added C. Karmarsch, the fracture is more fine-grained the more the metal has been mechanically worked. In conformity with R. Hooke's seventeenth century observations of the crystalline characters of the metals, aluminium cast from the liquid state is an aggregate of *allotriomorphic* (ἀλλότριως, strange; *μορφή*, form) crystals since the shape of each crystal is determined by the crowding of the neighbouring crystals; no *idiomorphic* (ἴδιος, characteristic) crystals, which have developed their characteristic form without being disturbed by other crystals, have been obtained. H. St. C. Deville said:

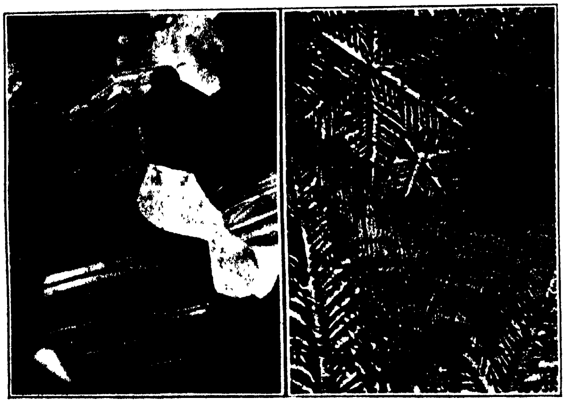
> Aluminium often presents a crystalline appearance when it has been cooled slowly. When it is not pure, the little crystals which form are needles, and cross each other in all directions. When it is almost pure it still crystallizes from fusion, but with difficulty, and one may observe on the surface of the ingots hexagons which appear regularly parallel along lines which centre in the middle of the polygon. It is an error to conclude from this observation that the metal crystallizes in the rhombohedral system. It is evident that a crystal of the regular system may present a hexagonal section; while, on the other hand, in preparing aluminium by the battery at a low temp., I have observed complete octahedrons which were impossible of measurement, it is true, but their angles appeared equal. When a large mass of molten aluminium is slowly cooled, and the fluid interior poured out, distinct octahedrons may be observed. Surface depressions are found in an ingot of commercial aluminium where the metal has solidified last. There are numerous dendrites in these depressions, and these pass gradually into the normal granular structure. On the sides and base of the ingot where it has cooled in contact with the mould, leaf-like dendrites stand up above the surface; they represent the first points of solidification. W. Campbell showed that the structure is best examined by casting the metal on a smooth cold surface—

F. and W. Mylius, *Zeit. anorg. Chem.*, **114**. 27, 1920; J. Czochralsky, *Zeit. Metallkunde*, **15**. 273, 1923.

[11] J. Billitzer, *Ber.*, **35**. 1933, 1902; T. Svedberg, *ib.*, **38**. 3618, 1905; F. Ehrenhaft, *Anz. Akad. Wien*, **39**. 241, 1902; D. Zavrieff, *Zeit. phys. Chem.*, **87**. 507, 1913; O. Ohmann, *Ber.*, **45**. 2973, 1912; C. H. Hall, *Journ. Amer. Chem. Soc.*, **44**. 1246, 1922.

Figs. 11 and 12 (×30), by W. Campbell. The dendritic structure shown in Fig. 12 was obtained by casting the metal on a surface of stone. The dendrites are composed of two axes at right angles to one another, and as a rule only one quadrant of the dendrite reached perfect development. S. Kryropoulos found different parts of a piece of aluminium to exhibit differences in electric potential with respect to a soln. of potassium ferrocyanide.

The dendritic forms of aluminium crystals led H. Behrens, and F. Rinne to assume that the crystals are similar to those of iron, being octahedral and belonging to the cubic system. H. St. C. Deville also stated that regular octahedral crystals are formed when the metal was prepared by the electrolytic process. **X-radiograms** by A. W. Hull, W. L. Bragg, F. Kirchner, H. Bohlin, F. Rinne, E. A. Owen, and G. D. Preston, F. Körber, K. Becker and F. Ebert, W. H. Bragg, N Uspensky and S. Konohejewsky, and P. Scherrer show that the unit structure of the aluminium crystal is that of a face-centred cube of side 4·04 to 4·05 A. with an atom of aluminium at each corner, and one at each face of the cube. The closest approach of the atoms is 2·35 A. S. Nishikawa and G. Asahara, H. Mark and K. Weissenberg, and M Ettisch and co-workers studied the effect of rolling and annealing on the X-radiogram of aluminium. H. C. H. Carpenter and C. F. Elam also prepared crystals of aluminium with a face-centred cube lattice. According to W. L. Bragg, the radius of the atomic spheres is 1·35 A. K. F. Slotte gave $6·6 \times 10^{-9}$ cms. for the edge of the mol. cube of solid and liquid aluminium. C. Davisson and C. H. Kunsman made observations on the structure of the atom. C. J. Smithells found the fracture of single crystals to be of the wedge type.



Figs. 11 and 12.—Crystals showing on the Surfaces of Cast Aluminium.

Commercial aluminium has not the high degree of purity of commercial copper, and may contain about 99·2 per cent. of aluminium; the impurities are mainly iron and silicon. While the structure near the surface of an ingot is dendritic, the internal structure is allotriomorphic, and the one type of structure passes more or less abruptly into the other. According to R. J. Anderson,[2] the grains of aluminium, with any copper present in solid soln., and iron as iron aluminide, $FeAl_3$, segregate at the grain boundaries, and the silicon, when free, appears to be inter- and intragranular. Both F. J. Brislee and R. J. Anderson believe that aluminium loses its crystalline structure when cold worked, and becomes amorphous. The former said:

> Microscopic examination of polished and etched specimens taken at various stages of cold-working shows that the crystalline structure disappears at a very early stage of the working,

and unless the metal is annealed, it will become fatigued, developing a species of *Forcierkrankheit*. Aluminium which has been subjected to excessive cold-working shows an entire absence of structure, and has the appearance of the metal which has flowed and passed into a vitreous amorphous state. . . . No modification of the customary methods of polishing and etching revealed elongated crystal boundaries such as are visible in other worked metals.

Au contraire, H. C. H. Carpenter and C. F. Elam followed the gradual elongation of the crystals from the cast ingot during the process of rolling; the metal finally appears to be a mass of parallel fibres running in the direction of the rolling. "The crystals in the cold-rolled sheet are so flattened out as to resemble the leaves of a book." A section cut transversely to the direction of rolling "would cut these leaf-like crystals in such an irregular manner that the structure revealed on etching would be very difficult to interpret." The idea that the cold-worked metal is amorphous is mainly due to difficulties in etching the metal. A. G. C. Gwyer, and W. Rosenhain do not believe that the metal becomes amorphous when severely deformed; although the latter thinks that the distorted grains in the highly deformed metal may not be accurately described as crystals, and that there must be a large proportion of disarranged—amorphous matter.

J. W. Mallet said that highly purified aluminium is less hardened by working metal which is less pure. When aluminium is strained slip-bands are formed, but, according to R. J. Anderson, no twinning has been so far observed as the result of direct mechanical strain. The slip-bands are produced by a sliding or slipping within the crystals, and they make themselves evident as fine straight or curved lines on the faces of individual crystals subjected to a stress exceeding the elastic limit. Fig. 13 (×1000) shows the slip-bands in 97 per cent aluminium developed by the deformation of the polished metal etched with sodium hydroxide. Two sets of bands are developed within individual grains, and they cross one another at an angle approximately 65°. Slip-bands are to be distinguished from the so-called Neumann-bands which are outcrops of mechanically twinned lamellæ formed by deformation.

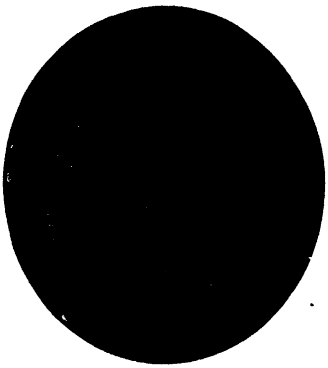


FIG. 13. Slip-bands in Aluminium (Etch: NaOH; ×1000).

The preparation of aluminium for microscopic examination has been described by D. Hanson and S. L. Archbutt, O. F. Hudson, R. J. Anderson, etc. Sodium or potassium hydroxide—in 0·10 to 20 per cent. soln.—is a common etching liquid; H. C. H. Carpenter and C. A. Edwards used 10 per cent. sodium hydroxide. The tarnished surfaces, due to carbonaceous matter, sometimes obtained are then cleaned with 60 per cent. nitric acid, or with chromic acid as recommended by W. Rosenhain and S. L. Archbutt. H. C. H. Carpenter and C. F. Elam preferred an alcoholic soln. of sodium hydroxide diluted with water until a stream of bubbles rises from all over the surface; followed by a 1–2 per cent. soln. of hydrofluoric acid. F. J. Brislee recommended hydrofluoric acid—in 10 to 15 per cent. soln. —the darkening of the surface is cleared by a few seconds' immersion in conc. nitric acid. Hydrofluoric acid tends to develop a pitted surface.

The hot-working of aluminium leaves the metal in a more or less strained condition since the finishing temp. is not usually high enough to effect the self-annealing of the metal. In the manufacture of sheet-aluminium, the metal is first worked hot, and finally rolled to gauge when cold. Z. Jeffries and R. S. Archer gave 150° as the lowest temp. at which the recrystallization of the cold-worked metal has been observed. H. C. H. Carpenter and C. F. Elam found that the recrystallization of the cold-worked metal is excessively slow at 200°, and very rapid in the neighbourhood of 600°. Recrystallization is very incomplete after eighteen months' heating at 200°, and the new crystals are confined to the surface of the metal sheet. There is *a gradual blurring of the original boundaries of the flattened crystals.* In the early *stages of recrystallization between 250° and 300°, new crystals appear at the old boundaries; these crystals appear white, the old un-reoriented crystals appear tarnished.* An hour's heating at 600° produced large polyhedral crystals which were approximately equiaxial although there was a slight tendency for them to be slightly elongated in the direction of rolling. The elongation of the new crystals in the direction of the rolling is more pronounced in the metal annealed, say at 250°–300°, than it is in the metal annealed at 450°–600°. G. Tammann found that the size of the crystals decreases as the temp. is raised, reaching a minimum between 300° and 500°, and after that the size increases with temp. Fig. 14 (×50), by R. J. Anderson, shows the appearance of an etched surface of aluminium annealed by four hours' exposure at 595°.

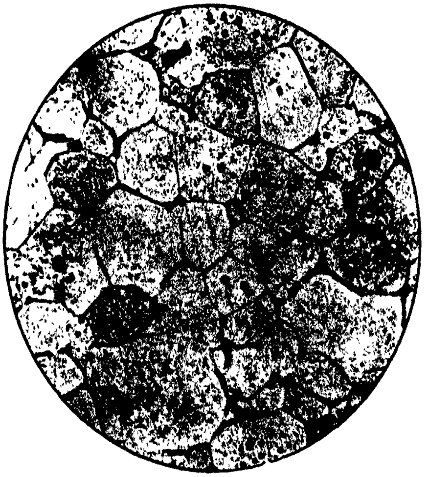

FIG. 14.—Allotriomorphic Crystals of Annealed Aluminium (Etch: HF; magnification × 50).

As a result of the work of C. Chappell on iron, of C. H. Mathewson and A. Phillips on α-brass, and of H. C. H. Carpenter and C. F. Elam on aluminium, and an alloy of tin with 1·5 per cent. of antimony, it is concluded that the recrystallization of strained metals does not take place as a result of the general disintegration of the distorted crystals. H. C. H. Carpenter and C. F. Elam inferred:

(1) Neither crystal growth nor recrystallization will take place unless the metal has been subjected to plastic deformation in the absence of a change of phase, and unless the metal has been heated to a certain minimum temp. for a certain minimum time.

(2) The effect of work depends on the amount of deformation and results in the production of twins, or slip-bands, or both followed; (i) neither by growth nor recrystallization on heating; (ii) by crystal growth on heating; nor (iii) by recrystallization and growth on heating.

(3) The degree of deformation which will produce these effects depends on the temp. The higher the temp. the less the required deformation. The effects produced by deformation are limited in extent, and depend on the amount of deformation, the annealing temp., and the period of heating.

(4) Recrystallization begins in crystal boundaries of old distorted crystals or in twin

boundaries. It starts from a few points and gradually spreads indiscriminately through the mass growing into the crystals in contact with the boundaries. The new crystals may exhibit twinned forms. No preference for growth in crystal boundaries or in twinning planes could be detected.

(5) Recrystallization is always followed by the growth of reoriented crystals into one another. Crystals can both grow and be grown into at the same time. A large crystal does not necessarily invade a small one with which it is in contact. A large crystal can grow at the expense of a small one, and conversely. Growth always occurs by boundary migration, not by coalescence. Neither similarity nor diversity of orientation affects the growth of one crystal into another. The size of the crystals when equilibrium is attained may vary within wide limits.

A. Sauveur, W. E. Ruder, C. Chappell, Z. Jeffries, and D. Hanson showed that if a metal be locally deformed and then heated, the largest crystals are produced at some distance from the point where the stress is most severe. R. Seligman and P. Williams, and G. Tammann and Q. A. Mansuri made some observations on the growth of the crystals. H. C. H Carpenter and C. F. Elam found that if the metal be locally deformed the largest crystals are always formed at the minimum stress requisite to produce growth; and the lower the temp. of heating, the greater the stress required to produce the largest crystals obtainable at that temp. It was suggested that the mechanical deformation supplies the energy for crystal growth, and that heat permits only those changes to take place which deformation has rendered possible; consequently the more the crystals are strained the greater the energy they possess. They found that as deformation increases the size of the crystals diminishes, because growth starts from more instead of fewer centres. Heating aluminium of 99·6 per cent purity to 550° for six hours, then subjecting it to a load of 2·4 tons per sq. in., and annealing the metal by raising its temp. from 450° to 550° at the rate of 15°–20° per day, and finally heating for one hour at 600°, sometimes gave pieces containing only one crystal. E. von Gomperz discussed this subject. E. Rassow and L. Velde represented the relations between the average grain-size of the allotriomorphic crystals of aluminium expressed in mm., the annealing temp., and the amount of cold-work expressed as a percentage reduction in the height of cm. cubes under compression, by means of a three dimensional diagram, Fig. 15. E. Wetzel also studied this question. E. C. Bain and Z. Jeffries investigated by X-radiographic examination whether deformation is accompanied by a rotation of crystal fragments or by the production of new orientations, and came to the latter conclusion. M. Ettisch and co-workers say that the crystallites in soft wires are arranged irregularly, and those in hard-drawn wires regularly. E. von Gomperz made wires of single crystals of aluminium. The alleged deterioration of aluminium after repeated melting was shown by W. Rosenhain and J. D. Grogan to be due to the progressive contamination of the aluminium by other materials. K. Bornemann and F. Sauerwald found that the application of press. did not increase the grain-size during the annealing.

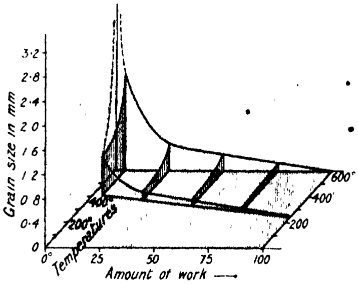

FIG. 15.—Effect of Work and Temperature on the Grain-size of Aluminium.

The **specific gravity** of aluminium is very small in comparison with that of ordinary metals, being nearly one-third that of iron; wt. for wt., therefore, aluminium occupies three times the vol. of iron, or vol. for vol., iron is nearly three times as heavy as aluminium. J. W. Mallet[3] gave 2·583 for the sp. gr. of the highly purified metal at 4°. The less pure metal usually has a higher sp. gr., but the increase is not proportional to the amounts of impurity present. According to J. W. Richards:

Composition Al	97·60	95·93	94·16	78·00
Composition Si	0·60	2·01	4·36	16·00
Composition Fe	1·80	2·06	1·48	4·00
Sp. gr. calculated	2·61	2·61	2·59	2·66
Sp. gr. observed	2·735	2·800	2·754	2·85

The calculated sp. gr. is always less than the observed, showing that a contraction occurs on alloying. Silicon has a smaller sp. gr. than aluminium. Assuming the total volume of impure aluminium is equal to that of the pure metal, it follows that the aluminium can be alloyed with several per cent. of iron and silicon and yet decrease in volume. According to F. Wöhler, the sp. gr. of cast aluminium is 2·50, and that of the hammered metal is 2·67; H. St. C. Deville gave respectively 2·56 and 2·66 for the cast and rolled metal; C. Karmarsch, 2·730 2·769 for commercial cast aluminium, 2·77 for thick sheet, and 2·798 for thin sheet. W. H. Barlow gave 2·688 for aluminium bars; E. Madelung and R. Fuchs, 2·7080; H. Buff, 2·664–2·667 for aluminium wire between 6° and 9°; and C. H. Hirzel gave 2·75 at 4·5° for the hammered metal. All this shows that the mechanical working of aluminium increases its sp. gr. J. D. Edwards and T. A. Moormann found that excessive cold work lowers the sp. gr.; thus, the sp. gr. of a sample of 99·5 per cent. aluminium drawn into wire, of No. 10 gauge, was 2·703 before annealing, and 2·7063 after annealing. G. W. A. Kahlbaum and E. Sturm found 2·713 for the sp. gr. of commercial aluminium; 2·703 for the metal, free from silicon, annealed at 470°, and 2·699 for the same metal cold-worked – all the data in vacuo at 20°/4°. F. C. A. H. Lantsberry gave 2·6995 for the cold-worked metal and 2·7030 for the annealed metal. For aluminium with 0·25 per cent. each of iron and silicon, F. J. Brislee found the sp. gr. of the cast metal to be 2·7080 at 14°–19°/4°; for hard drawn rod, 2·7052 at 22°/4°; and for the re-melted metal, 2·6821 at 16°/4°, the decrease may have been due to the adsorption of gases, say nitrogen. T. M. Lowry and R. G. Parker found the sp. gr. of filings of purified aluminium is rather less than that of the metal *en masse*, falling from 2·7040 to 2·7027. They showed further that although the complete annealing of worked aluminium is accompanied by a contraction, there is a slight expansion in volume in the earlier stages of the process of annealing at 100°. H. St. C. Deville said that heating the rolled metal to 100° had very little influence, for the sp. gr. was lowered from 2·67 to 2·66. J. W. Richards stated that heating a sample almost to its m.p., and then suddenly chilling it with water lowered its sp. gr. from 2·73 to 2·69. Annealing restores the sp. gr. of the worked metal to its original value; thus, J. D. Edwards and T. A. Moormann found the sp. gr. (in vacuo) of cast aluminium (99·75 per cent. Al) at 20° to be 2·703; and 2·703 when rolled and annealed. T. M. Lowry found the sp. gr. of aluminium is decreased by annealing at 100°. The best representative value for the sp. gr. of annealed aluminium is 2·703, and for the cold-worked metal 2·700. E. Heyn and E. Wetzel found that quenched aluminium suffers no perceptible change in vol. on standing. K. Bornemann and F. Sauerwald measured the sp. vol. of aluminium and its copper alloys. P. Pascal and J. Jouniaux gave 2·41 for the sp. gr. of aluminium at the m.p. in an atm. of an inert gas, 2·36 at 800°, and 2·29 at 1000°. J. D. Edwards and T. A. Moormann measured the sp. gr. (in vacuo) of aluminium up to 1100°, *A* with 99·55 per cent. Al; *B* with 99·4 per cent. Al; and *C* with 98·25 per cent. Al, and found:

	Solid				Liquid			
	20°	100°	400°	659°	659°	700°	900°	1100°
Sp. gr. *A*	2·703	2·69	2·62	2·55	2·382	2·371	2·316	2·262
Sp. gr. *B*	2·706	—	—	—	2·384	2·373	2·318	2·264
Sp. gr. *C*	2·727	—	—	—	2·405	2·394	2·339	2·285

The sp. gr. of 99·75 per cent. aluminium, when molten at θ°, is D=2·382

$-0{\cdot}000272(\theta-658°)$. The sp. gr. of 99·75 per cent. aluminium at different temp. is plotted in Fig. 16.

There is a vol. change of 6·6 per cent. in passing from liquid to solid at the f.p. J. W. Richards gave 2·66 for the sp. gr. of commercial aluminium at ordinary temp., and 2·54 when melted. It is this solidification shrinkage which is responsible for the pipe formed in an ingot during freezing. H. Endo found a 6·26 per cent. change in vol. on melting. M. Täpler found 2·70 for the sp. gr. at 20°, and at the m.p. 2·426; this corresponds with a 4·8 per cent. expansion on melting; otherwise expressed, a gram of metal expands 0·019 c.c. J. H. Chamberlain observed an expansion during the freezing of aluminium; and a contraction when the metal is melted. This he attributed to the presence of gaseous impurities. H. A. Wilson found the **ratio of mass to weight** is the same for bismuth and aluminium to within one part per million.

H. St. C. Deville said that the **hardness** of cast aluminium is about the same as that of cast silver; and C. Karmarsch found silver wire will scratch cast aluminium.

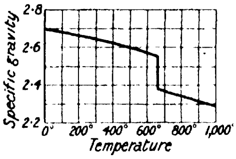

FIG. 16.—Specific Gravity of Aluminium at Different Temperatures.

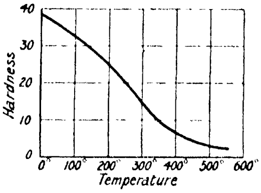

FIG. 17.—The Variation of the Hardness of Aluminium with Temperature.

J. W. Mallet found that highly purified aluminium is softer than the less pure metal, and is between 2·0 and 2·5 on Mohs' scale; it cannot therefore be scratched with the finger-nail, and it is not so soft as tin. The 99 per cent. metal, said J. W. Richards, can be readily cut with a knife, but the 95 per cent. metal is cut with difficulty. Aluminium becomes surface hardened by cold working, so that cold drawing or rolling makes aluminium nearly as hard as brass. Assuming the hardness of copper is 100, J. W. Richards gives 47 for the hardness of cast aluminium, and 62 for that of the rolled metal—the hardness of cast brass is 71, rolled brass 86. The hardness of aluminium on J. R. Rydberg's scale is 2·9 when that of copper is 3·0, and that of silver 2·7; and on F. Auerbach's scale of absolute values, the hardness of aluminium is 52 when that of silver is 91. S. Bottone gave 0·0821 for the hardness of aluminium, 0·1360 for copper, and 0·0990 for silver. The effect of temp. has been examined by P. Ludwik, and A. Kürth; the former found the viscosity hardness to vary with temp. as illustrated in Fig. 17. J. Okubo found the scleroscopic hardness of aluminium to be 3·75 when that of lead is 1·35. He also measured the **coefficient of restitution** on impact. The Brinell hardness of cast aluminium varies from 23 to 28; according to P. D. Merica, the scleroscopic hardness of annealed and cast aluminium varies from 4 to 6; the hardness of cold-rolled sheets varies from 13 to 15. R. J. Anderson measured the scleroscopic hardness of a number of sheets of hard aluminium, and found:

Thickness in mm.	0·2291 (3)	0·1215 (8)	0·1037 (10)	0·0841 (12)	0·0650 (14)	0·0169 (26)
Hardness	5·0	12·5	14·0	15·0	15·0	15·0

where the numbers in brackets refer to the sheet gauge. The effect of annealing is illustrated by selecting the results with sheet of 10-gauge. After 120 mins.' heating to 200°, the hardness was 10·2; after 30 mins. at 350°, the hardness was 5·0; and

	300°			400°				600°
Time in mins.	10	30	60	5	10	30	60	10
Hardness	10·0	7·0	5·0	10·6	5·0	4·8	4·5	4·0

M. Hanriot found that the Brinell's hardness of aluminium was raised from 14·6 to 19·0 after the metal had been compressed at 10,000 kgrms. per sq. mm. H. J. Coe gave for Brinell's hardness of cast aluminium, 23; for extended and drawn aluminium, 26–29; and for the metal annealed at 550°, 17·5–24·0. H. O'Neill measured the hardness of single crystals of aluminium. Z. Jeffries detected no change in the microstructure after the metal had been subjected to compression.

As shown by D. Saito and K. Hayashi,[4] the fluidity of molten aluminium is large. K. Honda and S. Konno found the **viscosity** of the rolled metal at 20° to be $0·723 \times 10^8$ to $0·822 \times 10^8$; and for the metal annealed at 400°, $1·25 \times 10^8$ at 20°. K. Iokibe and S. Sakai found the viscosity of annealed aluminium to be $25·50 \times 10^8$ at 15°. S. W. Smith found the **surface tension** of molten aluminium between 700° and 820° to be 520 dynes per cm., and the **capillary constant** $a^2 = 45·09$ per sq. mm. I. Traube gave 119,300 megabars or 10^6 dynes per sq. cm. for the **internal pressure** of solid aluminium; and T. W. Richards, 126,000 megabars. J. H. Hildebrand and co-workers calculated relative values for the internal press. of the metals; and C. E. Guye and co-workers measured the effect of temp. on the viscosity. W. J. Humphreys studied the **diffusion** of aluminium in mercury; R. J. Anderson, of copper in molten aluminium, and G. Sirovich and A. Cartoceti, and O. Bauer and E. Piwowarsky, of aluminium in solid copper. A. Masson gave 5104·5 metres per second for the **velocity of sound** in aluminium. J. W. Mallet found that the highly purified metal is not sonorous, but the less purified is highly sonorous. H. St. C. Deville reported: "A very curious property which aluminium shows is its excessive **sonorousness**, so that a bar of it suspended by a thin wire and struck, sounds like a crystal bell. The sonorousness is the more pronounced the purer the metal. A bell cast with the metal gave a sharp sound of considerable intensity, but which was not prolonged, and it seemed as if the clapper or support hindered the sound, which was thus far from agreeable." A. Springer said with respect to the use of aluminium for sounding boards:

> Aluminium differs from all other metals in the absence of the comparatively continuous and uniform higher partial tones which give in other metals the tone-colour called metallic; and further, that it possesses an elasticity capable of sympathetic vibration uniformly through a wide range of tone-pitch, which renders it in this respect superior to wood.

The **malleability** of aluminium is high. It can be forged and rolled as readily as silver and gold, and as F. Wohler, H. St. C. Deville, and M. Degousse [5] showed, it can be beaten out into thin leaf. J. W. Richards said that commercial aluminium leaf is 0·000638 mm. in thickness, and compares favourably with ordinary silver-leaf. J. W. Mallet said that highly purified aluminium is more malleable than the less pure metal. In rolling, the more impurity in the metal the less readily can it be worked, and the quicker does it become hard. According to J. W. Richards, more than 1 per cent. of iron makes aluminium less and less malleable until with 6 per cent. of iron the metal is brittle; on the other hand, up to nearly 10 per cent. of silicon can be present without rendering the metal unfit for rolling. Aluminium is most malleable between 100° and 150°, and, according to C. Fabian, the metal is best worked in that range of temp., for it can be worked some time at that temp. before hardening. If rolled cold, it requires more frequent annealing. Annealed aluminium is one of the softest and most pliable of metals, yet, as H. St. C. Deville stated, by hammering it becomes as hard and elastic as iron; and, according to A. R. von Burg, by cold working it can be given the stiffness and temper of brass. Aluminium leaf is rubbed to powder and sold as a metallic dust for decorative purposes. C. Margot found that melted aluminium poured on glass sticks very tenaciously on cooling. J. Czochralsky studied the effect of occluded gases on the mechanical properties of aluminium.

Gold, silver, platinum, iron, and copper are said to be the only metals whose **ductility** is greater than that of aluminium. H. St. C. Deville noted that aluminium can be drawn into fine wire. The metal quickly hardens at the drawing plate, and requires frequent annealing. The larger sizes of wire can be drawn warm, and they then require less annealing. Aluminium can be punched and stamped in dies. The elongation in the tensile strength test can be regarded as a measure of the ductibility --Figs. 14 to 17. P. D. Merica gave for the ductility of soft annealed aluminium sheets of different thickness, by Erichsen's test :

Thickness .	0·0126	0·0201	0·0319	0·0508	0·0808	0·1018 mm.
Ductility .	5·5 7·5	7·0 8·0	7·5 9·0	9·0 10·5	10·5-12·0	11·0-12·5

W. H. Barlow found the ductility of cold-worked aluminium to be relatively small —2·5 per cent. According to H. St. C. Deville, aluminium can be filed without choking the file, but C. Karmarsch showed that the converse is true. W. C. Heraeus said that aluminium may be welded.

Cast aluminium has not a high **elasticity,** and in this respect it resembles cast silver ; when worked, however, it becomes more rigid and elastic. If the hardened metal be re-heated to about 600°, and slowly or quickly cooled, it becomes almost as soft and pliable as lead. If re-worked, the metal again becomes stiff and elastic. According to W. Voigt, the **modulus of elasticity** or **Young's modulus** of longitudinal elasticity of cast aluminium is 6750 kgrms. per sq. mm. G. Angenheister gave 6716 kgrms. per sq. mm. for the annealed, and 7074 kgrms. per sq. mm. for the hardened metal. For the cold-worked metal, K. F. Slotte gave 7200 ; G. S. Meyer, 7462 ; and N. Katzenelsohn, 7540 kgrms. per sq. mm. F. J. Brislee found for Young's modulus of 99·3 per cent. aluminium in bars $9{\cdot}84\times10^6$ lbs. per sq. in. ; in wires, $9{\cdot}79\times10^6$ lbs. per sq. in. the average is $9{\cdot}8\times10^6$ lbs. per sq. in. W. Sutherland gives 680×10^{-6} grms. per sq. cm. as the best representative value at 15° with the extremes 602×10^{-6} and 753×10^{-6} grms. per sq. cm., and he represents the value of Young's modulus at θ by $E_0(1-0{\cdot}823\theta)/T_m)$, where T_m represents the m.p. of the metal ; and E_0, the value of Young's modulus at absolute zero. H. L. Dodge found with annealed wire of 99·29 per cent. aluminium and silicon 0·24 per cent., iron 0·44 per cent., and copper 0·03 per cent., the effect of temp. on Young's modulus, $E'=E\times10^{-11}$ dynes per sq. cm., and the temp. coeff., $\alpha=10^{-11}dE/dT$, to be :

	20°	40°	60°	80°	100°	120°	140°	160°	180°
E' .	7·50	7·40	7·27	7·10	6·90	6·66	6·38	6·06	5·72
α .	0·0046	0·0057	0·0072	0·0090	0·0112	0·0135	0·0155	0·0165	0·0170

With hard wire the results were rather lower, but there was a partial annealing at the higher temp. The temp. coeff. of the hard wire was almost constant. H. L. Dodge concluded that annealing does not materially affect the value of Young's modulus, but it does affect the rate of change, increasing the temp. coeff. for low temp. and decreasing it for higher values. C. Schäfer found the elastic modulus increased 21·32 per cent. per 100° in falling from 20° to −186°. According to J. Pionchon, just before the m.p., i.e. between 580° and 625°, aluminium acquires a granular structure, becoming very friable and falling to powder on the slightest press. ; and A. Granger found that when aluminium is heated to a temp. of about 600°, its tenacity and hardness become greatly modified, the metal assumes a grained structure, and can be easily broken. On heating to a still higher temp., the metal can be cut with a knife or even crushed in a mortar. According to J. W. Richards, the presence of 2 to 5 per cent. of copper, nickel, silver, or titanium raises the elasticity without noticeably affecting its sp. gr., or impairing its malleability. W. Rübel found that from 4 to 7 per cent. of phosphorus raised the elasticity, sp. gr., and tenacity of aluminium. K. A. Schreiber examined the influence of different elements on the properties of aluminium.

For the **torsion modulus,** rigidity, or shear modulus of aluminium, C. Schäfer gave 2329, N. Katzenelsohn 3350, and F. Horton 2605 kgrms. per sq. mm. ; for cast aluminium, W. Voigt gave 2580 kgrms. per sq. mm., and for the cold-worked metal, H. Tomlinson gave 2673 kgrms. per sq. mm. For the absolute values between 0° and 20°, W. Thomson gave 2410 kgrms. per sq. mm., and H. Tomlinson 2470-2400 kgrms. per sq. mm. W. Sutherland gave 0·932 0·943 for the ratio of the rigidity at 100° to that at 0°, and 0·803 for the ratio at 200° and 0°. At 15°, W. Sutherland takes the best representative value as 2500 kgrms. per sq. mm., and for the rigidity, N, at $\theta°$, $N/N_0=1-(\theta/T_m)^2$, where T_m denotes the absolute m.p., and N_0 the rigidity at absolute zero. C. Schäfer represents the percentage decrease with temp. on cooling as 30·2. K. R. Koch and C. Dannecker found for the influence of temp. on the torsion modulus (lbs. per sq. in.):

	20°	100°	200°	300°	400°	450°	500°
Torsion modulus $\times 10^{-6}$	3·87	3·73	3·45	3·10	2·63	2·03	0·68

W. H. Barlow[6] found that a rolled bar of aluminium had a **tensile strength** of 26,800 lbs. per sq. in., and an elongation before breaking of 2·5 per cent. He added that the tenacity is almost equal to that of steel if the comparison be made by weight. C. Karmarsch, P. Ludwik, F. Haber and R. Geipert, A. G. C. Gwyer, E. A. Hunt and co-workers, H. J. Coe, H. L. Dodge, and many others have measured this constant. P. D. Merica gives for softened or *normalized aluminium*, *i.e.* aluminium which has been mechanically worked by rolling, drawing, or forging, and then annealed at 400°, the average tensile strength 12,500–15,000 lbs. per sq. in., or 8·78–10·54 kgrms. per sq. mm.; with the yield point 8000–9000 lbs. per sq. in., or 5·52–6·32 kgrms. per sq. mm. and an elongation in 2 ins. of 10·40 per cent., and a reduction in area of 20–30 per cent. He also gives the results indicated in Table II for different forms of the metal. E. Wilson and J. Gavey found that the *duration of stress* or the time occupied in applying the tensile stress, has a marked influence on the result. Thus, with hard-drawn aluminium wires with a breaking load of 325 lbs. and a tensile strength of 25·3×10³ lbs. per sq. in. under ordinary conditions, by varying the time of the application of the breaking load, they obtained:

TABLE II.—TENSILE PROPERTIES OF ALUMINIUM.

Form of metal.	Tensile strength lbs. per sq. in.	Yield point lbs. per sq. in.	Percentage elongation in 2 ins.	Percentage reduction in area.
Sand cast	11,000–13,000	8,500	15–25	—
Chill cast	12,000–14,000	9,000	15–25	—
Sheet: Annealed	12,000–15,000	8,000–9,000	12–35	20–30
Semi-hard	18,000–22,000	9,000–12,000	5–12	20–30
Hard	22,000–25,000	12,000–25,000	1–7	20–30
12-gauge	25,000	—	7	—
16-gauge	28,000	—	5	—
20-gauge	30,000		3	—
Bars, hard	28,000–35,000	14,000–23,000	—	30–40
Wire: Hard	25,000–55,000	16,000–33,000	—	40–60
40-mil	31,000		—	—
80-mil	28,000	—	—	—
120-mil	25,000	—	—	—
200-mil	22,000	—		—

Time of application, secs.	0·5	5	118	525
Breaking load	300	280	240	220
Tensile strength	23·3	21·8	18·7	17·1

and the wire was not broken, but still stretching at the end of 1900 hrs. Hence, about two-thirds the nominal breaking load caused rupture when applied continuously for about three weeks. H. Shoji found that the relation between the time t and the torsion angle x can be represented by $x=c/t^a$, or $x=a-b\log t$ when a, b, and c are constants. K. L. Meissner discussed this subject.

When aluminium has been strained beyond the elastic limit, it suffers plastic deformation with any increase of stress—*vide* copper. A. Morley and G. A. Tomlinson showed that the metal recovers from this overstrained state if allowed to rest for about 14 days; the recovery is accelerated by raising the temp., but the recovery with the warmed metal is not so complete as the slower recovery at the lower temp. The rate of recovery from overstrain is not affected by the transverse or longitudinal vibrations produced by hammering. A. Elmendorf measured the effect of *alternating stresses* on the tenacity of aluminium which normally had a tensile strength of 15,000 lbs. per sq. in. If S denotes the fibre stress, and n the number of reversals required for rupture, then $S=48{,}000n^{-0{\cdot}113}$. Hence, a million reversals are required for rupture with a fibre stress of 10,000 lbs. per sq. in., and ten million reversals for rupture with a fibre stress of 7800 lbs. per sq. in.

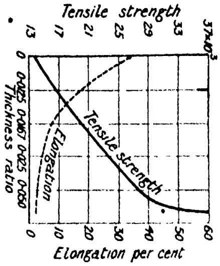

FIG. 18. Effect of Cold-working on the Tensile Properties of Aluminium.

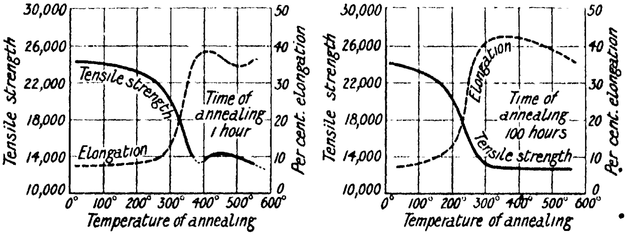
According to P. D. Merica, the *cold-working* of aluminium increases the tensile strength, and decreases the elongation or ductility. Representing the amount of cold-work in terms of the reciprocal ratio of the thickness of the sheet tested divided by the thickness of the original sheet, the percentage elongation in 2 ins. and the tensile strength in lbs. per sq. in.$\times 10^{-3}$ are shown in Fig. 18. H. C. H. Carpenter and L. Taverner examined the *rate of annealing* or softening of cold-rolled aluminium sheets by annealing at different temp., and for different periods of time. The impurities in the metal were silicon 0·75, iron 0·34, and copper 0·03 per cent. Selections from the results are shown in Figs. 19 and 20. The general conclusions were: (1) The hardness caused by mechanical work is lost very rapidly upon annealing at from 300° to 500° C. The same final tensile strength of about 12,700 lbs. per sq. in. is obtained in all cases. (2) The softening is most marked within the first portion of the annealing period. (3) No hardening by annealing was noticed as in the case of copper and brass. (4) Below 300°, the decrease in hardness is very slow, but occurs within the temp. range of 100° to 200° with no increase of ductility.



FIGS. 19 and 20.—The Annealing of Cold-worked Aluminium.

A. G. C. Gwyer showed that the tensile strength and elongation increase rapidly as the *grain-size* decreases, Fig. 21, but with a grain-size finer than from 200–300 grains per sq. mm., the tensile strength and elongation are almost indifferent to the size of grain. The effect of *temperature* on the tensile properties of aluminium has been studied by P. Breuil, R. Baumann, H. le Chatelier, and G. D. Bengough. The results by the last-named with 99·56 per cent. aluminium are shown in Table III

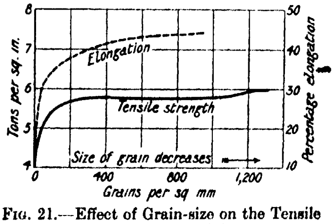


FIG. 21.—Effect of Grain-size on the Tensile Properties of Aluminium.

TABLE III.—THE EFFECT OF TEMPERATURE ON THE TENSILE PROPERTIES OF ALUMINIUM.

Temperature of test.	Tensile strength in lbs. per sq. in.	Percentage elongation in 2 ins	Percentage reduction in area.
20°	19,200	12	75
200°	14,100	15	78
275°	11,110	17·2	79
330°	7,600	20·3	88
375°	3,800	25	88
396°	2,150	56	90
450°	—	65	96
520°	900	88·5	To finest possible point.
565°	540	70·3	
610°	660	75·0	
625°	420	39·0	92

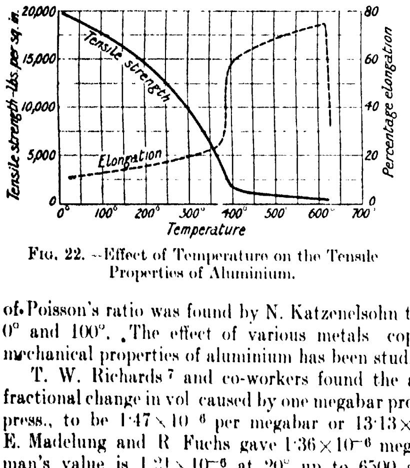

FIG. 22.—Effect of Temperature on the Tensile Properties of Aluminium.

and Fig. 22. There is a well-marked change in direction in the stress-temp. curve at about 395°, and at a rather lower temp. with the strain-temp. curve. The metal becomes plastic just over 600°. G. Pisati and co-workers represented the tensile strength of aluminium at $\theta°$ between 0° and 100° by $50·8-0·0458\theta-0·000372\theta^2$ kgrms. per sq. mm., and between 100° and 200° by $54·7-0·12\theta$. **Poisson's ratio,** that is, the ratio of the transverse contraction to the longitudinal extension under a tensile stress, is 0·359 according to C. Schäfer, and 0·363 according to P. Cardani. The value of Poisson's ratio was found by N. Katzenelsohn to increase 15·7 per cent. between 0° and 100°. The effect of various metals—copper zinc, tin, and iron—on the mechanical properties of aluminium has been studied by M. Wahlert.

T. W. Richards[7] and co-workers found the average **compressibility,** *i.e.* the fractional change in vol caused by one megabar press. between 100 and 500 megabars press., to be $1·47\times10^{-6}$ per megabar or $13·13\times10^{-8}$ per at. vol. per megabar. E. Madelung and R Fuchs gave $1·36\times10^{-6}$ megabars per sq. cm. P. W. Bridgman's value is $1·21\times10^{-6}$ at 20° up to 6500 atm. press.; J. W. Buchanan's $1·67\times10^{-6}$ at 9° and 256 atm.; S. Lussana gave for press. up to 2000 atm.:

	14·7°	27°	71°	103°	126°
Compressibility coeff.	$0·88\times10^{-6}$	$0·96\times10^{-6}$	$1·03\times10^{-6}$	$1·10\times10^{-6}$	$1·18\times10^{-6}$

and E. Grüneisen gave for press. between 10 and 150 atm. $1·32\times10^{-6}$ at $-191°$; $1·48\times10^{-6}$ at 15°; and $1·80\times10^{-6}$ at 125°. L. H. Adams and co-workers gave $1·39\times10^{6}$ per megabar for the compressibility of aluminium; and they represented the change in vol., δv per c.c., produced when the press. changes from p_0 to p, by $\delta v=-1·2\times10^{-4}+1·325\times10^{-6}(p-p_0)$. According to P. W. Bridgman, if v denote vol. at $\theta°$ at atm. press., and the change in vol., δv, by application of a press. p kgrms. per sq. cm. is $\delta v/v\times10^7$ at 30° is $-13·40p+3·5\times10^{-5}p^2$ for hard drawn rod; for annealed drawn rod at 30°, $-13·34p+3·5\times10^{-5}p^2$, and at 75°, $-13·91p+3·5\times10^{-5}p^2$; and for the cast metal at 30° $-13·43p+5·0\times10^{-5}p^2$, and at 75°, $-13·76p+5·1\times10^{-5}p^2$. P. D. Merica gives 6,000–25,000 lbs. per sq. in. for the elastic limit of aluminium under press., and 16,000–100,000 lbs. per sq. in. for the ultimate strength; A. Elmendorf found 67,000 lbs. per sq. in. for the ultimate strength of cast aluminium. P. W. Bridgman found that the linear change, δl, in the length l when the press.

is p kgrms. per sq. cm. is $\delta l/l = 0{\cdot}0000003910p - 0{\cdot}0000056$. C. J. Burton and W. Marshall observed a rise of 0·181° on compressing aluminium at 388 atm. press., this corresponds to a rise of 0·00047° per atm. H. J. Coe found the maximum load giving critical plasticity to be 5·16 tons per sq. in. for cast aluminium; 7·00 to 7·40 tons per sq. in. for extruded and drawn metal; and 6·41 to 6·50 tons per sq. in. for the metal annealed at 550°. E. H. Dix studied the **impact** test on aluminium.

According to H. Fizeau,[8] the coeff. of **thermal expansion,** α, of aluminium is 0·00002313 at 40°, and 0·00002336 between 0° and 100°; P. Glatzel gave $\alpha = 0{\cdot}00002354$; and F. C. Calvert and R. Johnson, $\alpha = 0{\cdot}00002218$ between 0° and 100°. H. L. Dodge found $\alpha = 0{\cdot}000025$ for wires with 99·29–99·39 per cent. of aluminium, 0·32–0·41 per cent. of iron, 0·22–0·24 per cent. of silicon, and 0·03–0·07 per cent. of copper, hard or soft. H. le Chatelier found 0·0000246 at 63°, and 0·0000315 at 600°; and F. Henning found 0·00002441 between 16° and 250°, and 0·00002717 between 16° and 500°; and 0·00001835 between 16° and −191°. F. J. Brislee showed that the thermal expansion is determined by the *history of the metal*, for if l denotes the length at θ when l_0 is the length at 0°, $l = l_0(1 + 0{\cdot}000024328\theta)$ for hard-drawn aluminium, and $l = l_0(1 + 0{\cdot}000024548\theta)$ for annealed aluminium between 0° and 100°. Hence, the coeff. of expansion, $\alpha = 0{\cdot}0_42454$, for annealed aluminium is slightly higher than $\alpha = 0{\cdot}0_42432$, for hard-drawn aluminium. W. Dittenberger gave for the expansion, δl, of aluminium in mm. per metre, between 0° and 610°, $\delta l = 0{\cdot}023536\theta + 0{\cdot}000007071\theta^2$; and K. Scheel between −78° and 500°, $\delta l = 0{\cdot}0229\theta + 0{\cdot}000009\theta^2$. The last-named found the linear expansion, δl, of aluminium between 0° and θ°, in mm. per metre:

	−78°	0°	100°	200°	300°	400°	500°
δl . . .	1·73	0	2·38	4·94	7·68	10·60	13·70

J. Disch made some observations at low temp. W. H. Souder and P. Hidnert found for the coeff. of linear expansion, α:

	20°–100°	100°–200°	200°–300°	300°–400°	400°–500°	500°–600°
α .	0·00002375	0·00002575	0·00002715	0·00003000	0·00003260	0·00003605

or $l = l_0\{1 + (21{\cdot}90\theta + 0{\cdot}0120\theta^2)10^{-6}\}$. They gave between 20° and 300°, $\alpha = 0{\cdot}0_4256$; between 300° and 600°, $\alpha = 0{\cdot}0_43290$; and between 20° and 600°, $\alpha = 0{\cdot}0_4294$. W. Voigt found for the effect of *temperature*, $\alpha\times10^6 = 23{\cdot}06 + 0{\cdot}61(\theta - 30)$, for 97·53 per cent. aluminium containing 1·33 per cent. of iron, 1·01 of silicon, and 0·17 of carbon. E. Grüneisen, and S. Lussana measured the effect of temp. and *pressure* on the coeff. of expansion, the former found for atm. press. $\alpha\times10^6$ is 68·49 between 17° and 100°, and 54·66 between 17° and 190°; the corresponding values for 1000 kgrms. per sq. cm. press. are 65·51 and 55·35 respectively. For atm. press. S. Lussana found $\alpha\times10^6 = 67{\cdot}11$ between 27° and 71°, and 68·25 between 27° and 126°; at 1000 atm. 64·71 and 65·88 respectively, and at 2000 atm. press., 62·58 and 63·55 respectively. For the proportional change of the thermal expansion, α, with press., p, P. W. Bridgman gave $-d\alpha/\alpha dp = 1{\cdot}02\times10^{-5}$ for cast aluminium, and $1{\cdot}76\times10^{-5}$ for the drawn and annealed metal.

Gold, silver, and copper are the only metals with a higher **thermal conductivity** than aluminium. F. C. Calvert and R. Johnson[9] found that if the conductivity of silver be 100, that of aluminium is 66·5. L. Lorenz found the thermal conductivity of aluminium to be 0·3445 cal. per cm. per sec. per degree at 0°, and 0·3619 cal. at 100°, so that if the conductivity of copper be 100, that of aluminium is 47·7 at 0°, and 50·0 at 100°. A. C. Mitchell's value, 0·6188 at 18°, is too high. W. Jäger and H. Diesselhorst obtained 0·4803 at 18° and 0·4923 at 100° with aluminium wire containing 0·5 per cent. of iron, and 0·4 per cent. of copper. The temp. coeff. is +0·29 per cent. According to C. H. Lees, the variation of the conductivity with temp. has a minimum about −125°.

	18°	0°	−50°	−100°	−125°	−150°	−160°	−170°
Conductivity	0·504	0·502	0·496	0·492	0·491	0·508	0·514	0·524

R. Schott measured the low temp. conductivity of aluminium. S. Konno found that the thermal conductivity of aluminium decreases with rise of temp. up to the m.p.; there is then an abrupt decrease. According to J. W. Richards, the thermal conductivity of annealed aluminium, 38·87 (silver, 100), is rather greater than that of the unannealed metal, 37·96 (silver, 100).

The **specific heat** of aluminium is higher than that of the common metals. This might be anticipated from its low at. wt. and Dulong and Petit's rule. Many values have been given for the sp. ht. of aluminium. H. V. Regnault[10] found 0·2056 between 25° and 97°, but his metal contained only 88·35 per cent. of aluminium. H. St. C. Deville said that H. V. Regnault asked for a sample in order to determine its sp. ht., but in spite of the warning that the available sample was very impure, H. V. Regnault persisted, and H. St. C. Deville added:

> It is a pity that I gave such impure material to serve for determinations of such splendid precision, and I was persuaded to do so only by the entreaties of M. Regnault, who could not wait until I had prepared him better material.

Possibly, H. V. Regnault had not recognized so clearly as H. St. C. Deville the importance of working with purified materials. In another determination with 97 per cent. aluminium, he obtained 0·2122 between 14° and 97°. H. Kopp used a sample with 2 per cent. of iron and obtained 0·2070 between 20° and 52°. J. W. Mallet found the sp. ht. of highly purified aluminium to be 0·2253. The *temperature coefficient* of the sp. ht. is higher than that of the common metals. H. Tomlinson represented his results for the mean sp. ht. from 0° to θ° with commercial aluminium by $0·2070+0·000115\theta$; A. Niccari, by $0·2116+0·00009507\theta$ from 0° to 300°; J. W. Richards, by $0·2220+0·00005\theta$ from 0° to θ° up to 600°, and $0·2220+0·0001\theta$ at θ°. W. Bontscheff represented his results at θ° between −75° and 500° by $0·20890+0·00016186\theta-0·0_6294246\theta^2+0·0_9461182\theta^3$, and his observations show that the sp. ht. of aluminium increases with rise of temp., and that the rate of increase decreases to a minimum between 200° and 300°, and thereafter increases. W. A. Tilden measured the mean sp. ht. of aluminium for ranges of temp. between 182° to 435°; and E. H. and E. Griffiths, between −114·3° and 97·6°. Other observations have been made by C. C. Trowbridge, R. Laemmel, H. C. Schmitz, P. Nordmeyer, E. Grüneisen, H. Schimpf, U. Behn, T. W. Richards and F. G. Jackson, J. A. Harker and H. C. Greenwood, W. Louguinine, and F. Glaser. W. Nernst and co-workers made some observations at temp. down to −253·9°, and P. Schübel up to 601°. The following is a selection from these results for C_p:

	−253·9°	−184·7°	114·3°	−81·5°	0·1°	97·6°	303°	500°	601
Sp. ht.	0·066	0·0967	0·1709	0·1867	0·2096	0·2248	0·2293	0·2363	0·2447

The first value is due to W. Nernst and F. Schwers, the second to W. Nernst and F. A. Lindemann, those above 97·6° are by P. Schübel, and the remainder by E. H. and E. Griffiths. The last-named also estimated values of the **atomic heats,** C_p and C_v, over the range −240·6° to 107°, or 32·4° K. to 380° K.

°K.	32·4°	50°	100°	160°	200°	250°	300°	340°	380°
C_p . .	0·25	0·91	3·08	4·64	5·14	5·54	5·81	5·98	6·13
C_v . .	--	—	3·05	4·56	5·03	5·37	5·57	5·69	5·79

The variation in the at. ht. at low temp. was found by W. Nernst and F. Schwers to be in agreement with P. Debye's formula, $C_v=8·4T^3$. F. J. Brislee showed that the results of many sp. ht. determinations are more or less fortuitous because the sp. ht. is determined by the thermal history of the metal; for example, the sp. ht. of annealed 99·6 per cent. aluminium is 0·2240 ± 0·0004 between 20° and 200°, and 0·2354 ± 0·00033 between 20° and 300°, while the sp. ht. of fresh hard-drawn wire is 0·2220 in the range 10° to 100°, and the value decreased after 10 days at 100° to 0·2150.

J. Pionchon found that with 99·1 per cent. aluminium the **thermal capacity,** or the amount of heat, Q, required to raise a gram of the metal from 0° to θ° is

$Q=0·393\theta-291·86\theta/(1517·8+\theta)$ up to 580° ; and for the liquid, from 630° to 800°, $Q=0·308\theta-46·9$. The sp. ht. thus rises slowly but with increasing rapidity from 0·201 at 0° to 0·2894 at 550°. The sp. ht. of the molten metal at 650° is 0·308. J. W. Richards represented the amount of heat in 99·93 per cent. aluminium at θ° up to 600° by $Q=0·2220\theta+0·00005\theta^2$; and he estimates the sp. ht. of the solid at the m.p. to be 0·285 ; J. Pionchon's value is 0·308. U. J. J. le Verrier reported that the sp. ht. of commercial aluminium is constant, 0·22 between 0° and 300° ; constant, 0·30, between 300° and 530° ; between 530° and 560°, there is an absorption of about 10 cals. ; and between 540° and 600°, the sp. ht. is again constant 0·46. No other observer has been able to verify U. J. J. le Verrier's remarkable statements. It is, however, to be noted that at about 600° aluminium begins to soften, and some latent heat is absorbed before the true m.p. P. N. Laschtschenko found that with aluminium containing 0·31 per cent. of silicon, and 0·63 per cent. of iron, but no copper or lead, the curve connecting the temp. with the amount of heat required to raise the temp. of 1 grm. of metal from any given temp., is continuous up to 580°, and is slightly convex towards the temp. axis, Fig. 23; between 580° and 590° there is a marked change in the direction of the curve corresponding with the pasty condition of the metal; and at 650°–670°, there is a sudden increase in the amount of heat, owing to the fusion of the metal. The high sp. ht. of aluminium, coupled with a large heat of fusion, causes the metal to melt very slowly even in a hot fire; and conversely on cooling. R. Ariano studied the heating and cooling curves of the metal. J. W. Richards showed that the amounts of heat required to raise a gram of a number of metals to the m.p. and then to melt them, are:

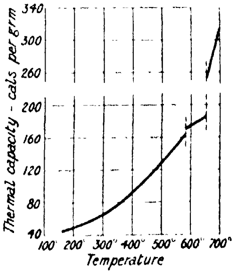

FIG. 23.—Thermal Capacity of Aluminium at Different Temperatures.

	Al	Fe	Cu	Pt	Ag	Au
Thermal capacity .	258·3	250·0	162·0	102·4	85·0	58·0 cals.

G. N. Lewis and co-workers, and E. D. Eastman gave 6·82 for the **entropy** of aluminium at 25° and atm. press. W. M. Latimer discussed the entropy changes in the metal electrons.

Aluminium fuses at a relatively low temp. ; H. St. C. Deville[11] said that the **melting point** lies above that of zinc, and below that of silver, but is nearer to that of zinc than to that of silver. R. Pictet gave 600° for the m.p. ; F. Heeren, and T. Carnelley, 700° for aluminium with 4–5 per cent. of iron ; P. H. van der Weyde, 850°. H. Rose said that pure aluminium is more fusible than the impure metal, but J. W. Mallet said that the converse is true, and H. le Chatelier has shown that a very small proportion of iron or silicon lowers the m.p.—*e.g.* aluminium with 0·75 per cent. and 1·50 per cent. of silicon melts at 619° ; but a large proportion of these impurities acts in the opposite direction. Outside the early difficulties in measuring what are now known as pyrometric temperatures, there are difficulties, as P. Rohland showed, arising from the presence of impurities, and from the masking of the true m.p. by the prior pasty condition ; and, as C. Matignon, and W. von Bolton showed, a protective film of oxide may be formed which permits aluminium wire to be heated above its m.p. without losing its shape. C. T. Heycock and F. H. Neville gave 654·54° ; S. W. Holman, R. R. Lawrence, and L. Barr, 660° ; H. L. Callendar, 654·5 ; W. R. Mott, 657·3° ; H. Gautier, 660° ; L. Holborn and A. L. Day, 657·3° ; A. L. Day and R. B. Sosman, 657° ; C. W. Waidner and G. K. Burgess, 658° ; A. L. Day, R. B. Sosman, and E. T. Allen, 658·0° ± 0·6° ; G. K. Burgess, 658° ± 1. The best representative value is 658·7° as given by L. I. Dana and P. D. Foote ;

W. Guertler and M. Pirani gave 658°; and F. Wüst and co-workers, 657°. W. Spring reported that aluminium powder flows to a solid mass at ordinary temp. under a press. of 38 tons per sq. in. If the liquid phase can escape, the m.p. of all metals are lowered by press. J. Johnston calculated that the press. necessary to melt aluminium at 27° is 5100 atm. R. C. Smith observed signs of sintering with aluminium filings at 200°.

H. St. C. Deville said that aluminium is non-volatile; it loses no weight when violently heated in a carbon crucible in a forge furnace. The volatilization of aluminium was noted with the introduction of electric furnaces. H. Moissan volatilized the metal in such a furnace, and he noted that if the vapour above the crucible be condensed on a copper tube through which cold water is passing, small spherules of the metal are obtained. H. C. Greenwood said that the **boiling point** of the metal at atm. press. is about 1800°; W. R. Mott also gave 1800°; and H. von Wartenberg, below 2200°. W. G. Duffield estimated the rate of evolution of molecules from the boiling liquid. J. W. Richards estimated the **vapour pressure** of solid aluminium at 0° to be $1\cdot0\times10^{-43}$ mm., and at the m.p., $5\cdot25\times10^{-7}$ mm., or $\log p$ $-14190/T+8\cdot98$; and the vap. press. of the liquid at $T°$ K. is $\log p$ $-15650/T+8\cdot4$. The latent **heat of fusion** of aluminium is very near that of ice. J. Pionchon found 78·9 cals. per gram, and P. N. Laschtschenko, 71 cals. per gram. F. Wüst and co-workers gave 93·96 cals. per gram. J. W. Richards estimated the latent **heat of vaporization** to be 2107 2305 cals per kgrm. R. Pohl and P. Pringsheim made mirrors of aluminium by condensing the vapour on a quartz plate.

The **refractive index,** μ; **the index of absorption,** k, such that the amplitude of a wave after travelling one wave-length, λ, measured in the metal, is reduced in the ratio $1:e^{-2\pi k}$, or for a distance S in the ratio $1:e^{-2\pi Sk/\lambda}$; and the percentage **reflecting power,** R, of aluminium have been measured by G. Quincke.[12] The values headed with an asterisk are by P. Drude:

λ	·431	·486	·527	·589	·589*	·630*	·656μ
μ	0·78	0·93	1·10	1·28	1·44	1·62	1·48
k	2·85	3·15	3·39	3·66	5·23	6·44	3·92
R	72·3	72·8	72·4	72·5	72·7	72·4	72·6

W. W. Coblentz also gave for the percentage reflecting power:

λ	1·0	2·0	4·0	7·0	10·0	12·0
R	71	82	92	96	98	98

J. Schumann and L. Mach studied the reflection of light of wave-length 1850–2800 on alloys of magnesium and aluminium; I. C. Gardner found aluminium reflects very poorly in the Schumann region. E. O. Hulbert also made observations on this subject. M. Faraday found that a film of aluminium in **polarized light** depolarized the ray, and brought in a red image which was reduced to a minimum by the rotation of the analyzer and then converted to a blue. S. Procopiu studied the optical effects of aluminium powder suspended in toluene. J. H. Gladstone gave 9·7 for the atomic **refraction equivalent** of aluminium with the H_a-line. W. J. Pope gave 14·61 for the at. refraction with the D-line.

According to W. H. Bragg,[13] the stopping power of aluminium for the **α-rays** is 1·45 (air unity). H. R. von Traubenberg gave $40\cdot6\times10^{-4}$ cms. for the range of the α-rays from radium-C in aluminium. E. Rutherford and J. Chadwick obtained evidence of the emission of long-range particles possibly hydrogen—when α-rays pass through aluminium. J. A. Crowther gave 5·26 for the ratio of the coeff. of absorption of β-rays and the density of the metal; and W. J. Russell and F. Soddy gave 0·111 per cm. for the coeff. of absorption of the **γ-rays** from radium; 0·130 per cm. for the uranium rays; 0·092 per cm. for thorium rays; and 0·119 for the mesothorium rays. J. Neukirchen gave $0\cdot0872\pm0\cdot0011$ for the scattering coeff. of aluminium for the γ-rays from radium-C. R. Whiddington, K. W. F. Kohlrausch, F. K. Richtmyer, W. Duane and K. C. Mazumder, P. A. Ross, C. G. Barkla and C. A. Sadler,

C. W. Hewlett, A. R. and W. Duane, E. H. Kurth, and H. G. J. Moseley studied the action of **X-rays** on aluminium, and the excitation of these rays by aluminium. The X-ray spectrum has been studied by E. H. Kurth, H. Kulenkampff, H. Bohlin, A. H. Compton, F. Horton and co-workers, etc. The *K*-series was measured by E. Hjalmar, and H. Fricke, who found, in Angström units, or 10^{-8} cm. units, $\alpha_2\alpha'$ and $\alpha_1\alpha=8\cdot31940$; $\alpha_3=8\cdot26460$; $\alpha_4=8\cdot25300$; $\alpha_5=8\cdot20580$; $\alpha_6=8\cdot18920$; $\beta'=8\cdot025$; $\beta_1\beta=7\cdot94054$; W. Duane and K. C. Mazumder, E. Rutherford, M. Ishino, S. J. Allen and L. M. Alexander, and A. W. Hull and M. Rice, measured the absorption of X-rays. J. A. Becker studied the effect of a magnetic field on the absorption of X-rays; R. Whiddington, the velocity of the electrons liberated by the action of X-rays; and F. K. Richtmyer, the absorption of X-rays by aluminium. The last-named found $\mu/D=5\cdot32$, and $\mu=1\cdot37$; C. W. Hewlett, $\mu/D=5\cdot17$, and $\mu=2\cdot30$; and C. E. Taylor, $\mu/D=5\cdot15$, and $\mu=2\cdot29$. F. K. Richtmyer found a discontinuity in the X-ray spectrum for very short wave-lengths, and inferred the existence of characteristic J-radiations. J. C. McLennan and M. L. Clark gave 123·3 for the critical voltage for the L-series of X-rays from aluminium. G. Schearer sought a relation between the at. number, and the number of electrons emitted by metals exposed to the X-rays.

V. C. Gyllenskold, J. Stark and G. von Wendt, H. Smith, and E. Beckmann and H. Linder studied the effect of the **canal rays**. E. A. Bichat found that the **n-rays** are not absorbed by aluminium. In the electrolysis of soln. of sulphuric acid, hydrochloric acid, alkali hydroxides and chlorides, alum, etc., with an alternating current, and aluminium electrodes, a **luminescence** appears at the electrodes. With a current density of 0·06 amp. per sq. cm., the light is sufficient to enable print to be read. The light increases with increasing current density, but is diminished with a rising temp. With a direct current, the anode alone is luminescent. The phenomenon has been studied by F. Braun, W. von Bolton, H. N. Morse, E. Kielhauser, F. Eichberg and L. Kaher, W. Mitkewitsch, E. Kutsinikoff, and T. Tommasina. The **photoelectric effect** has been studied by W. Ramsay and J. F. Spencer, B. Aulenkamp, K. Herrmann, R. A. Millikan and G. Winchester, O. W. Richardson and K. T. Compton, A. L. Hughes, G. Reboul, T. C. Sutton, A. E. Hennings and W. Kadesch, J. R. Nielsen, R. Pohl and P. Pringsheim, and by O. von Baeyer and co-workers. W. Frese found the photoelectric sensitiveness to be greatly reduced after treatment with water or alcohol. R. Hamer found the limiting frequency of the photoelectric effect to be $\lambda=3596\pm100$. M. Hake found that colloidal particles of aluminium may become negatively charged by exposure to ultra-violet light; with aluminium *en masse* the charge is positive. L. Clémandot studied the **phosphorescence** of alumina. A. Nodon showed that an aluminium plate is opaque to ultra-violet solar radiations under conditions where a lead plate is permeable.

Aluminium compounds do not impart any colour to the non-luminous gas flame. W. N. Hartley and H. Ramage[14] have studied the spectrum produced by the oxyhydrogen flame. A. Masson first made some observations on the **spark spectrum** of aluminium. More accurate observations on the spark spectrum have been made by G. Kirchhoff, J. M. Eder, R. Grünter, R. Capron, W. A. Miller, R. Thalén, J. N. Lockyer, L. de Boisbaudran, A. S. King, J. Parry and A. E. Tucker, R. Seeliger and D. Thaer, G. D. Schallenberger, W. Spottiswoode, J. Dewar, W. N. Hartley, E. Fues, B. Hasselberg, F. McClean, J. M. Eder, E. Valenta, E. Demarçay, F. Exner, E. Haschek, G. A. Hemsalech, T. Tommasina, H. Konen, J. H. Pollok, A. G. G. Leonard, S. R. Milner, F. Paschen, etc. The most important lines in the visible spectrum are the yellowish-green lines at 572·3 and 569·6, the green line at 505·7, and the blue line at 466·2, Fig. 24. Many other lines are indicated in the Tables of wave-lengths. F. Brasack has stated that the presence of 0·00004 mgrm. of aluminium can be detected by the spark spectrum. The subject has also been studied by A. de Gramont. R. Bunsen thought that aluminium chloride gives no characteristic lines either in the flame or when sparked. An intense electric sparking is needed to detect small quantities. The **arc spectrum** of aluminium has been investigated by H. Kayser and C. Runge, W. Huppers, C. Ramsaur and F. Wolf, S. Procopiu, R. Grünter, L. Arons, O. H. Basquin, H. Crew and J. Spence, R. Seeliger and D. Thaer, J. C. McLennan and co-workers, etc. In the arc spectrum there is a number of characteristic bands which, as M. Guichard and P. R. Jourdain showed, disappear if the arc be surrounded by hydrogen. The **band spectrum** has been studied by A. de Gramont, R. Thalén, L. de Boisbaudran, A. J. Angström, C. Ciamician, G. A. Hemsalech, G. Berndt, J. Lauwartz, and H. Morris-Airey. L. C. Glaser found the structure of the band spectra of beryllium and aluminium to be similar. The bands in the **ultra-violet spectrum** are extremely characteristic, and they have been investigated by G. G. Stokes, W. H. Fulweiler and J. Barnes, A. Hörnli, R. A. Millikan, J. L. Schönn, A. Cornu, G. D. Liveing, J. Dewar, H. Deslandres, J. S. Ames, C. Runge, J. M. Eder, V. Schumann, and G. Berndt. The arc or spark discharge of aluminium under water gives an almost continuous spectrum, and W. Kasperowicz used it as a source of ultra-violet rays. The **ultra-red reflection spectrum** has been investigated by H. Becquerel, F. M. Walters, W. W. Coblentz, and F. Paschen. The percentage reflecting power of sheet aluminium for different wave-lengths is:

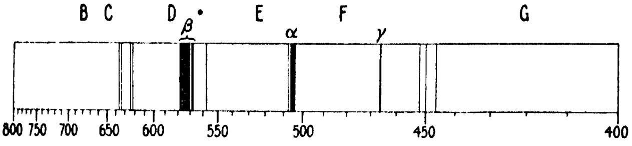

FIG. 24.—Spark Spectral Lines of Aluminium.

λ	1·06	3·06	5·24	8·02	10·49	12·03μ
Reflecting power	73·8	88·3	93·8	96·9	96·9	97·3 per cent.

The **enhanced lines** have been studied by J. N. Lockyer, and J. Steinhausen; the **reversed spectrum,** by A. Cornu, G. D. Liveing, and J. Dewar; the causes of the *variability of the spectrum*, by A. S. King; the *influence of the medium*, by H. Finger; the *effect of temperature*, by A. Wüllner; the *effect of pressure*, by A. Wüllner, and W. J. Humphreys; V. C. Gyllensköld, and J. Stark and R. Künzer, **the canal ray spectrum**; and the **Zeeman effect,** by H. M. Reese.

The **absorption spectrum** of aluminium vapour has been investigated by J. N. Lockyer and W. C. Roberts-Austen, W. Grotrian, and J. C. McLennan and co-workers; and of aluminium compounds in soln., by H. W. Vogel. The salt soln. of this element are colourless. H. W. Vogel showed that the absorption spectra of compounds of aluminium with some colouring agents is the best mode of applying the spectroscope to the detection of aluminium; a soln. of hæmatoxyline was found to be very suitable for the purpose; and J. Formanek said that tincture of alkanna is better. If a little aluminium salt be added to a soln. of alkanna when the reaction is completed, there is a prominent band at 585·7 and auxiliary bands at 542·5 and 504·8, as shown in Fig. 25.

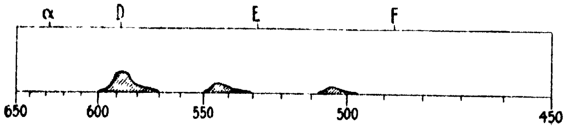

FIG. 25.—Absorption Spectrum of Alkanna and Aluminium Chloride.

The **series spectra** of aluminium have been studied by A. Cornu, E. Fues,

F. Paschen, G. D. Shallenberger, and H. Kayser and C. Runge. The last-named represented the two subordinate series of pairs of lines by the formulæ:

First Series.	Second Series.
$10^8\lambda^{-1}=48308\cdot2-156662m^{-2}-2505331m^{-4}$	$10^8\lambda^{-1}=48244\cdot5-127527m^{-2}-687819m^{-4}$
$10^8\lambda^{-1}=48420\cdot2-156662m^{-2}-2505331m^{-4}$	$10^8\lambda^{-1}=48356\cdot5-127527m^{-2}-687819m^{-4}$

The relations of these subordinate pairs of lines with gallium, indium, and thallium are illustrated by Fig. 25. The spectroscopic method of C. Runge and J. Precht for estimating the at. wt. by plotting logarithms of at. wt. with logarithms of the distances of two lines—doublet separation—of the series spectra of related elements, and finding what at. wt. for a particular member of the family of elements lies on a straight line, was shown by W. M. Watts to agree with the aluminium family of elements. The method is illustrated by Fig. 26. L. C. Glaser discussed the relationship between the spectra of beryllium and of aluminium. F. L. Mohler and A. E. Ruark found the **resonance potential** of aluminium vapour to be 0·014 for $2p_2-2p_1$; 3·129 for $2p_2-2s$; and 4·004 for $2p_2-3d_{1,2}$; and for the **ionization potentials**, $2p_2=5\cdot960$; and $2p_1=5\cdot946$. J. E. P. Wagstaff gave $\gamma=7\cdot5\times10^{12}$ for the **vibration frequency.** J. M. Eder studied the **actinic value** of the light from burning aluminium.

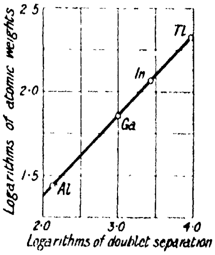

FIG. 26.—Relationship between the Spectral Lines and the Atomic Weights of Al, Ga, In, Tl.

C. Davisson and C. H. Kunsman[15] studied the **scattering of electrons** by aluminium. O. Edelmann found that for low voltages a layer of aluminium powder 8 mm. thick is practically a non-conductor; at 360 volts and upwards it conducts; and for the high voltages of frictional electricity, it may be regarded as a good conductor. R. D. Kleeman and W. Fredrickson found that if an electric current be passed through water in which aluminium and carbon are immersed, the aluminium acquires a negative charge.

A. T. Thomson, Lord Kelvin (W. Thomson), and H. St. C. Deville early noted that the **electrical conductivity** of aluminium is high. If the conductivity of copper be 100, J. C. Poggendorff said that the conductivity of aluminium is 51·3; and if that of silver be 100, A. Matthiessen said that the conductivity of aluminium is 33·76. Measurements were also made by H. Buff, M. Weber, G. K. McGee, L. Lorenz, A. Emo, L. Weiler, A. Stein, J. B. C. Kershaw, A. Arndtsen, W. Jäger and H. Diesselhorst, A. Schulze, etc. The earlier determinations are mainly of historical interest. The deviations in the determinations by different observers are largely due to (i) Variations in the purity of the metal used. Only in 1889 was metal of 99 per cent. purity in commerce. (ii) References to copper or silver as standards require a knowledge of the degree of purity, and the history of these metals. Errors also arise from the lack of accurate standards of resistance as well as imperfect methods of measurement. The general result shows that the electrical conductivity of aluminium is 60·3 per cent. of that of annealed copper. A. Sturm found the conductivity at 0° to be $35\cdot6\times10^4$ rec. ohms. Working with highly purified aluminium,

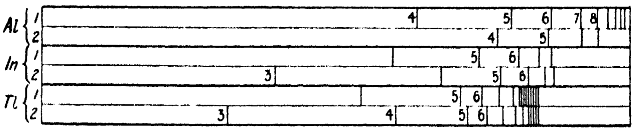

FIG. 27.—Series Spectra of Aluminium, Indium, and Thallium.

G. Niccolai found that the conductivity of aluminium, over a wide range of *temperature*, in reciprocal ohms, when that of mercury at 0° is $1{\cdot}063\times10^4$, is

	−189°	−100°	0°	100°	400°
Conductivity .	156×10^4	$65{\cdot}2\times10^4$	$38{\cdot}2\times10^4$	$25{\cdot}9\times10^4$	$12{\cdot}5\times10^4$

J. Dewar and J. A. Fleming gave for 99 per cent. commercial aluminium :

	−183°	−78°	0°	92·2°	101·5°
Conductivity .	$178{\cdot}6\times10^4$	$58{\cdot}7\times10^4$	$39{\cdot}0\times10^4$	$28{\cdot}3\times10^4$	$21{\cdot}6\times10^4$

J. W. Richards and J. A. Thomson found that annealed aluminium wire has a conductivity very nearly one per cent. greater than unannealed wire. E. F. Northrup measured the **electrical resistance** of 99·67 per cent. aluminium containing 0·16 per cent. silicon, 0·15 per cent. iron, and 0·02 per cent. of copper; and annealed by heating to redness, and cooling in air; and found 2·75 microhms per c.c. at 20°, and this increased linearly with temp. to 3·66 microhms at 100°. A. Somerville gave for the temp. coeff. of the resistance of aluminium wire between 18° and 100°, 0·0038; and at 25°, 0·00334; at 50°, 0·00337; at 100°, 0·00340; at 500°, 0·00350; and at 600°, 0·0060; L. Holborn gave 0·00445 between 0° and 100°. L. Cailletet and E. Bouty gave 0·00388 between −91° and 28°; J. Dewar and J. A. Fleming, 0·00390 between −100° and 0°; and 0·00423 between 0° and 100°. R. Benoit gave $R=R_0(1+0{\cdot}003876\theta+0{\cdot}0_51320\theta^2)$. For temp. in the vicinity of atm., the best representative value is 0·0039. J. W. Richards and J. A. Thomson found the best representative values of the resistances of hard and soft aluminium to be 2684 and 2659 per c.c. in C.G.S. units at 0°. W. Broniewsky gave $R=40{\cdot}1\times10^2(1+0{\cdot}004250\theta)$ for the resistance of hard aluminium at θ° between 0° and 100°; and $R=38{\cdot}5\times10^2(1+0{\cdot}004100\theta)$ for that of the soft metal. H. Tsutsumi found for the ratio of the conductivity of aluminium in the liquid and in the solid states at its m.p. to be 1·64.

P. W. Bridgman measured the effect of *pressure*, expressed in kgrms. per sq. cm., on the electrical resistance of 99·47 per cent. aluminium containing 0·23 per cent. of iron, 0·24 per cent. of silicon, and 0·06 per cent. of copper. The wire was annealed at 120°. The initial resistance was 18·7 ohms at 0°, and the temp. coeff. 0·00434.

		0	25°	50°	75°	100°
R		1·0000	1·1077	1·2159	1·3245	1·4337
Press. coeff.	0 kgrm. .	$0{\cdot}0_5416$	$-0{\cdot}0_5410$	$-0{\cdot}0_5405$	$-0{\cdot}0_5401$	$-0{\cdot}0_5397$
	12,000 kgrms.	$0{\cdot}0_5347$	$-0{\cdot}0_5349$	$-0{\cdot}0_5351$	$-0{\cdot}0_5354$	$-0{\cdot}0_5356$
	average .	$0{\cdot}0_53815$	$-0{\cdot}0_53794$	$-0{\cdot}0_53781$	$-0{\cdot}0_53772$	$-0{\cdot}0_53766$

The mean press. coeff. is $-0{\cdot}0_5416$ at 0°. W. E. Williams obtained $0{\cdot}0_537$. W. Fraenkel and E. Scheuer studied the effect of ageing on the properties of aluminium alloys. L. Guillet found the electrical resistance of commercial aluminium to be 2·8 micro-ohms per cm. cube, and with less pure metal, the resistance increases. Mechanical treatment increased the resistance slightly; and in tempering, the more rapid the quenching the higher the resistance. A. T. Waterman applied the electronic theory of conduction to aluminium.

Many reports [16] have been made on the uses of aluminium based on its relatively high electrical conductivity. A. L. Williams found that, unlike copper, aluminium does not fuse with mica to form a conducting mixture. O. Jaamaa and Y. E. G. Leinberg measured the resistance of powdered aluminium mixed with marble.

The electrode potential of aluminium has proved very difficult to measure accurately. In alkaline soln. commercial aluminium precipitates zinc, but not in neutral or acid soln.; amalgamated aluminium, however, does precipitate zinc from neutral soln., it vigorously decomposes water, rapidly oxidizes in air, and generally exhibits characters which place it in the electrochemical series directly after magnesium and the metals of the alkaline earths. This is taken to mean that commercial aluminium is in a passive state, otherwise expressed, it is more noble, and less active than the amalgamated metal. In attempting to measure the electrode potential, B. Neumann[17] obtained the best results with plates of aluminium cleaned with alkali-lye, and then rubbed while hot with mercury. No amalgam is formed, but the mercury mechanically held by the plates helps depolarization. With the cells Al | $Al_2(SO_4)_3$, Al | $AlCl_3$, and Al | $Al(NO_3)_3$ against KCl—Hg he found that the electrode potential of aluminium against the normal sulphate is +1·040 volts, the normal chloride +1·015 volts, and the normal nitrate +0·0775 volt. C. R. A. Wright and C. Thompson made some observations with aluminium against copper in a soln. of the sulphate; aluminium against cadmium in soln. of the chloride and bromide; and aluminium against zinc in soln. of the sulphate, chloride, and bromide. As a result, N. T. M. Wilsmore provisionally set up the **electrochemical series** of electrolytic potentials:

K	Na	Ba	Sr	Ca	Mg	Al	Mn	Zn . . .
+3·20	+2·82	+2·82	+2·77	+2·56	+2·54–1·49	+1 276	+1·075	+0·770 . . .

R. Müller and F. Hölzl studied the potential of aluminium and amalgamated aluminium in soln. of aluminium chloride, potassium chloride, hydrochloric acid, and sodium hydroxide. In 6·8*N*-HCl, aluminium is more electropositive than the amalgam. The anomalous behaviour under some conditions is attributed to a coating of oxide. F. H. Jeffrey studied the electrolyses of soln. of sodium nitrite, and of potassium oxalate with aluminium electrodes. F. Streintz and F. Fiala studied the polarity of the aluminium cell. N. R. Dhar measured the difference of potential of aluminium against soln. of potassium chloride, and found – 0·03 volt for the potential against water. C. M. van Deventer and H. van Lummel found that experiments on amalgamated aluminium also agree with this position for aluminium to the left of zinc. The inactivity of ordinary aluminium in a zinc | acid | aluminium cell is caused by a coating of aluminium oxide which with amalgamated aluminium is much less stable. The fact that this coating is a leaking insulator explains the abnormal electrical behaviour of ordinary aluminium. F. Streintz placed the elements in the order Mg, Zn, **Al**, Cd, Fe, Sn, Bi, Co, Sb, Cu, Ni, Hg, Pt, and Au. C. F. Burgess and C. Hambüchen found the potentials in volts of aluminium electrodes indicated in Table IV against a normal calomel electrode. They also tried mixtures of ammonium chloride with ammonium fluorides and with potassium fluoride. They infer that of these combinations aluminium fluoride is the best salt to use in connection with aluminium for battery purposes.

TABLE IV.—POTENTIALS OF ALUMINIUM ELECTRODES IN AQUEOUS SOLUTIONS (VOLTS)

According to E. Heyn, hardened aluminium is electropositive to the soft or annealed metal by about 0·03 volt in ordinary tap-water. H. Buff tried aluminium in Bunsen's cell; J. Regnauld, in the cell Zn | $ZnSO_4$, $Al_2(SO_4)_3$ | Al; F. Streintz studied the cells Zn | $Zn(NO_3)_2$, $Al(NO_3)_3$ | Al, and Zn | $ZnCl_2$, $AlCl_3$ | Al. F. Exner measured the potential difference with aluminium and soln. of the halogens, and the halide acids. F. Wohler studied the cell Al | conc. HNO_3, dil. NaOH | Al, and Al | conc. HNO_3, dil. HCl | Al; and V. Kistyakowsky measured the electrode potential of the cell Al | N-Al ions N-H ions | H_2 on platinum. F. Wöhler and H. Buff studied aluminium anodes in a soln. of sodium, ammonium, ferrous, or manganous chloride; the hydrogen is contaminated with spontaneously inflammable silicon hydride. V. Neyreneuf obtained a similar result on both aluminium electrodes by using an alternating current for the electrolysis. W. Beetz investigated the aluminium anode in dil. sulphuric acid Zn | $ZnSO_4$, H_2SO_4 | Al; and A. Coehn, in soln. of aluminium sulphate. H. T. Barnes and co-workers studied the behaviour of aluminium electrodes in water containing dissolved air, oxygen or hydrogen peroxide, and the abnormally high e.m.f. was connected with the presence of free oxygen in the water. The combination Mg | $Al_2(SO_4)_3$ | Al gave a considerable current which rose to about 2 volts if hydrogen peroxide was added.

H. Buff, and C. Wheatstone noted that aluminium as anode in nitric acid or other oxidizing soln. becomes **passive** and electronegative. According to E. Newberry, aluminium in alkali-lye becomes passive with a current density of 600 milliampères per sq. cm., giving an anodic overvoltage of 0·95 volt. When the current density is reduced to 400 milliampères per sq. cm. the overvoltage falls to 0·01 volt. Below this, the metal dissolves slowly. It cannot be passivated in sulphuric acid. A very thin, brass-coloured film forms on the surface of the passive metal and prevents the current density from rising above 600 milliampères per sq. cm. with an applied electromotive force of 8·2 volts. The **polarization** of the aluminium electrode has been studied by H. Buff, who attributed it to the formation of a layer of silicon owing to the use of impure aluminium; and W. Beetz, to a layer of suboxide. P. G. Tait, and E. Pirani measured the e.m.f. of the polarization. The attention of E. Ducretet, C. Pollak, L. Graetz, P. Askenasy, F. Kohlrausch, A. Overbeck, A. M. Scott, F. Streintz, A. Naccari, P. Straneo, A. Isenburg, K. E. Guthe, G. C. Schmidt, and A. Bartorelli has also been attracted to this subject. When an aluminium anode is used in passing a current through an aq. soln. and the press. does not exceed 20 volts, the current falls [illegible] to zero, probably owing to the formation of a layer of aluminium hydroxide. A. Smits and co-workers explain the strong positive character of the metal by assuming that primarily the metal surface becomes poor in ions and electrons, *i.e.* the metal at its surface passes into a metalloidal state and then has a low electrical conductivity. The oxygen separation and subsequent oxide formation are then secondary phenomena. They say that the commercial metal is not coated with a film of oxide, and that anodically polarized aluminium has no primary oxide layer. A. Günther-Schulze claims that this is opposed to known facts. R. Müller and F. Hölzl have investigated this subject. U. Sborgi and P. Marchetti studied the anodic behaviour of aluminium in a sat. soln. of lithium chloride in acetone. If a gradually increasing e.m.f. be used, F. Fischer showed that when the voltage attains a certain critical value, the coating on the anode is suddenly pulverized, and the current suddenly increases to 50 times its initial value. The critical voltage depends on the temp. and nature of the electrolyte; if a hollow anode be cooled internally the non-conducting layer will withstand 220 volts, when under ordinary circumstances 20 volts suffice to break it down. E. Lecher found that when the film is formed, the wire is heated, the film is a poor thermal conductor, and its temp. is raised until the soln. in the vicinity of the anode boils. K. Norden analyzed the film obtained when dil. sulphuric acid is the electrolyte and found 69·8 per cent. of alumina, 13·2 per cent. of sulphur trioxide, 14·8 per cent. of water, a few small particles of aluminium, and 2·2 per cent. of silica. The silica is probably derived from the oxidation of the silicon in the aluminium. A mixture of a basic sulphate and aluminium hydroxide, $Al_2O(SO_4)_2.H_2O+10Al(OH)_3$, with 9·25 per cent. of aluminium would have the same composition as the analysis.

W. W. Taylor and J. K. H. Inglis found that if a dil. sulphuric acid cell, in which the resistant film has been formed, be treated with potassium chloride, bromide, nitrate, chlorate, or thiocyanate, there is a ready passage of the current; potassium acetate does not act. They assume that the film of aluminium hydroxide which is formed is impermeable to $Al^{\cdots}$-ions and SO_4''-ions. They measured the rates of diffusion of these salts in aluminium hydroxide films, and also the effect of these salts on the rate of soln. of the hydroxide in sulphuric acid. Potassium bromide has very little influence on the solubility. A. Heydweiller gave 40 for the **speed of migration** of aluminium ions, and W. Ostwald gave 392 Cals. per valence for the **heat of ionization** of aluminium.

A. Günther-Schulze found that with two uniform aluminium electrodes the electrolysis of a soln. of sodium metaphosphate by an alternating current of 50 cycles furnishes oxygen and hydrogen as though each phase were present alone. No appreciable depolarization of the products of one phase is brought about by those of the next phase. R. D. Kleeman and W. Fredrickson studied the electric charge assumed by an aluminium wire immersed in a liquid. If a cell be constructed with a platinum and an aluminium electrode, with a sulphate, phosphate, or oleate as electrolyte, then during electrolysis with an alternating current, the current only passes in one direction when the aluminium is the cathode. The polarization when aluminium is the anode prevents the current passing. Hence, it is possible to utilize the phenomenon in obtaining a direct from an alternating current. The **aluminium rectifier,** or the **electrolytic valve action** of aluminium has been studied by S. B. Charters, A. Günther-Schulze and co-workers, G. E. Bairstow and R. Mercer, E. Wilson, A. Smits, etc. For the luminescence of the anode during electrolysis with an aluminium anode, *vide supra.* F. Fischer and O. Hähnel, and V. Kohlschütter and co-workers examined the disintegration of aluminium electrodes in the vacuum tube containing different gases. S. Kyropoulos studied the electrodeposition of copper, silver, chromium, and nickel on aluminium.

The values of the **thermoelectric force,** E, of the *aluminium-platinum* couple, determined by W. Jäger and H. Diesselhorst,[18] J. Dewar and J. A. Fleming, K. Noll, W. H. Steele, and E. Wagner, range from $+0{\cdot}37$ to $+0{\cdot}41$ millivolt per 100°. E. F. Northrup represented the e.m.f. of the *aluminium-copper* couple by $E\times10^6=4{\cdot}51-0{\cdot}0122\theta^2+0{\cdot}0000433\theta^3$ volts. For the *aluminium-silver* couple, W. M. Latimer found at 100°, dE/dT to be 3·7 microvolts per degree; at 200°, 4·4; at 300°, 5·0; at 400°, 5·9; at 500°, 7·5; and at 600°, 10·1 microvolts per degree. P. G. Tait obtained $-0{\cdot}68$ for the *aluminium-lead* couple at 20°, and $-0{\cdot}56$ microvolt at 50°; and $dE/d\theta=0{\cdot}0039\theta-0{\cdot}76$, so that the neutral point is 195°. P. W. Bridgman represents the results with purified and annealed aluminium for the Al-Pb couple: $E\times10^6=-0{\cdot}416\theta+0{\cdot}0_48\theta^2-0{\cdot}0_41\theta^3$ volts, and with commercial aluminium, $E\times10^6=-0{\cdot}378\theta-0{\cdot}0_45\theta^2+0{\cdot}0_594\theta^3$ volts; for the **Peltier effect,** P, respectively with these two couples, $P\times10^6=(-0{\cdot}416+0{\cdot}00016\theta-0{\cdot}0_43\theta^2)(\theta+273)$ volts, and $P\times10^6=(-0{\cdot}378-0{\cdot}0001\theta+0{\cdot}0_4282\theta)^6(\theta+273)$ volts; and for the **Thomson effect,** σ, respectively $\sigma\times10^6=(0{\cdot}00016-0{\cdot}0_46\theta)(\theta+273)$ volts per degree, and $\sigma\times10^6=(-0{\cdot}0001+0{\cdot}0_4564\theta)(\theta+273)$ volts per degree. The differences in the numerical constants are not large. The effects of press. on the thermoelectric force of a couple composed of one branch of uncompressed metal and the other branch of the same metal compressed to the press. indicated in kgrms. per sq. cm.:

		10°	20°	40°	60°	80°	100°
Press.	2,000 kgrms.	−0·031	−0·054	−0·073	−0·058	−0·002	+0·101
	4,000 kgrms.	−0·048	−0·081	−0·104	−0·060	+0·066	+0·294
	8,000 kgrms.	−0·070	−0·089	−0·046	+0·146	+0·478	+0·929
	12,000 kgrms.	−0·069	−0·068	+0·130	+0·543	+1·151	+1·962

The cold junctions were kept at 0°. The metal was specially purified. The e.m.f. is given in volts $\times10^6$. The reversals of sign are not considered to be due to the assumption of two modifications in varying proportions. The curves, *Metals*, **10.** 193, 1913; H. O'Niell, *ib.*, **30.** 299, 1923; H. § 5. The Chemical Properties of Aluminium

J. B. A. Dumas[1] found that when aluminium is gradually heated in vacuo, while the pump is active, **occluded gas** is released somewhat suddenly towards a red heat; 200 grms. of metal occupying 80 c.c. gave 89·5 c.c. of gas at 17° and 755 mm. press. The gas contained 1·5 c.c. of **carbon dioxide,** and 88 c.c. of **hydrogen**—carbon monoxide, nitrogen, and oxygen were absent. Gas is evolved when cathode rays are generated in evacuated tubes with aluminium electrodes. This subject has been studied by R. von Hirsch and F. Soddy. E. Cohnstädt said that the gas given off by aluminium electrodes is water vapour and not hydrogen, and added that glass and aluminium surfaces will retain water even when heated to 500° or dried over phosphorus pentoxide. J. Czochralsky studied the absorption of nitrogen, air, sulphur dioxide, oxygen, carbon monoxide and dioxide, hydrogen, and coal gas by aluminium. He found that molten aluminium does not begin to dissolve any of the common gases until about 900°, but at higher temp., considerable amounts may be dissolved, and retained in the form of minute blowholes in the solid metal. The following table shows the amounts of gas, in volumes per cent., dissolved at the high temp. and retained by the solid metal at ordinary temp.:

	N_2	O_2	Air	CO	CO_2	SO_2	H_2	Town gas
1200° . .	0·4	2·5	1·3	1·3	2·5	5·4	6·5	5·5
1500° . .	3	12	6	8	12	7	15	12·5

In the case of the first six gases very small amounts of the absorbed gases combine with the metal with formation of aluminium nitride, oxide, carbide or sulphide, and the metal structure shows characteristic inclusions of these constituents. The mechanical properties of the metal after treatment with any of the above gases showed practically no change, but in all cases blisters and splitting of the edges occurred during rolling. The most suitable temp. for rolling metal containing many gas-pores was found to be between 300° and 350°. G. Neumann and F. Streintz found that sheet aluminium absorbed 1·1 to 2·7 vols. of hydrogen at n.p.t.; the gas is absorbed when hydrogen is made the cathode in an electrolytic cell. H. G. Deming and B. C. Hendricks found aluminium to be impermeable to hydrogen at temp. up to 550°. E. Duter said that an *aluminium hydride* is formed during the electrolysis of distilled water with an aluminium cathode, and added that it is immediately decomposed by water. M. Guichard and P. R. Jourdain measured the gases evolved when old and new aluminium is heated in vacuo. The gas comes partly from the surface, and partly from the body of the metal. The proportion of carbon dioxide in the gases exhibits the most marked variation. A. Berliner found that at 440°, aluminium exercises no perceptible influence on the union of hydrogen and oxygen, due, he suggests, to the fact that aluminium occludes no appreciable quantity of hydrogen. F. Paneth and co-workers could find no evidence of the formation of an aluminium hydride.

Both F. Wöhler,[2] and H. St. C. Deville agree that "moist or dry **air** has no action on aluminium," and G. Werther said that he has kept sheet aluminium for many years exposed to air without being able to detect the formation of any oxide; but E. von Bibra found an impure sample was covered with oxide after being exposed to the air for some months. G. H. Bailey found the corrosive action of air or oxygen at ordinary temp. is negligibly small. H. St. C. Deville was enthusiastically emphatic on the resistance of aluminium to oxidation in air and oxygen:

> Aluminium may be melted in air with impunity, and therefore air or oxygen cannot sensibly affect it. The metal resisted oxidation at the highest temp. of a cupel furnace. When the metal button is covered with a layer of oxide which tarnishes it, the expansion of the melted metal causes small branches to shoot from its surface, which are very brilliant and do not lose their lustre in spite of the oxidizing atm. F. Wohler has also observed this property on trying to melt the metal with a blowpipe. E. M. Péligot has profited by it to cupel aluminium. I have seen buttons of impure metal cupelled with lead and become very malleable. With pure aluminium the resistance of the metal to direct oxidation is so considerable that at the m.p. of platinum it is hardly appreciably touched, and does not lose its lustre. It is well known that the more oxidizable metals take this property away from it; but silicon itself, which is much less oxidizable, when alloyed with it makes it burn with great brilliancy, because aluminium silicide is formed.

These statements give a wrong impression, and illustrate the danger of presenting a case like a skilled advocate before a jury, exalting the importance of evidence for one side, and belittling the evidence on the other. The proper attitude, of course, is to present the case as an impartial judge weighing fairly the evidence presented by both sides. H. St. C. Deville's position will be clear from the historical notes. J. W. Mallet said that pure aluminium is more readily oxidized in air than is the impure metal. In air, commercial aluminium gradually becomes coated with a thin film of oxide so that the metal soon loses its brilliancy and acquires a matte surface which gives it the appearance of old zinc. The film protects the metal from further oxidation. Air and rain-water also corrode aluminium. A. Liversidge said that "the surface becomes rough and speckled with grey spots mixed with larger light grey patches; it also becomes rough to the touch, the grey patches can be seen to project above the surface, and under the microscope, they present a blistered appearance. This incrustation is held tenaciously, and does not wash off, neither is it removed on rubbing with a cloth." The coating can, however, be removed by washing with dil. acid. When aluminium is melted in air, it acquires a surface film of oxide which restrains the free flow of the metal; this film also protects the melted metal from further oxidation. As H. Moissan showed, *aluminium burns* with a vivid incandescence when heated in the electric furnace, although here it is possible that the metal first volatilizes and it is the vapour which burns. Hence, a white cloud of alumina issues from high temp. electric furnaces in which aluminium is present.

H. Buff observes that fine pulverulent aluminium is soon oxidized by exposure to air. *N. B. Pilling and R. E. Bedworth found that at 600° there are two distinct stages in the oxidation of aluminium. A thin layer of oxide is slowly formed;* the process occupies 60–80 days. Oxidation then ceases because of the complete impenetrability of the film. The weight of the oxide film is 0·1 mgrm. per sq. cm., and it would be 0·00002 cm. thick if of normal density. F. Wöhler, and M. Degousse showed that aluminium-leaf burns brightly in air, and in oxygen, yielding a brilliant bluish light and forming alumina—C. Matignon found that in air some aluminium nitride is formed during the combustion. A. Duboin said some aluminium suboxide, AlO, is formed when a mixture of a mol of alumina and four gram-atoms of aluminium is ignited. According to W. Muthmann and K. Kraft, the ignition temp. of aluminium in oxygen is 580°. Aluminium foil and wire also burn in oxygen. According to F. Wöhler, aluminium foil is best ignited in oxygen by wrapping it round a splinter of wood. A. M. Villon showed that finely powdered aluminium burns brilliantly when projected into a flame, and has largely displaced magnesium powder for flash-light mixtures because it is cheaper; it gives almost as strong an actinic light, and does not give such unpleasant smoke or fumes—A. M. Villon recommended a mixture of 100 parts of aluminium, 25 parts of lycopodium, and 5 parts of ammonium nitrate. J. M. Eder has studied the actinic power of the light.

The aluminium dust of commerce is finely divided aluminium metal with a coating of oil, usually stearine or some similar material. This coating evidently serves to prevent oxidation in air and to protect the metal particles from the action of moisture, as it is stated that the product loses its lustre if no oil be added. Aluminium dust is so light that it is easily blown about a room, and, as the workmen seldom take precautions to prevent this, the workrooms are soon coated with dust. According to A. Leighton, experiments do not show the exact conditions under which an ignition of the aluminium dust is obtained, they do show that it may ignite at temp. even lower than those necessary for the ignition of coal dust; but more heat is needed to ignite aluminium dust. Hence precautions should be taken to prevent loose aluminium powder from being blown into the air.

In making aluminium powder, the metal is pounded in stamp-mills, sorted according to size of grain, and polished in polishing mills. Very fine sorts are subjected to a rubbing treatment after sifting and before polishing, by grinding the metal dust with a soln. of gum arabic. Serious explosions have occurred in the sifting and polishing machines, due apparently to the ignition of dust by accidental sparks in the machinery, so that, in order to minimize the danger, rules for use in factories making aluminium-bronze powders have been formulated, by *Der Suddeutsche edel- und unedelmetall Berufsgenossenschaft für die Herstellung von Aluminium in Pulver.* Ordinary aluminium bronze powders do not flash when blown through a flame, but the finer kinds can be ignited in this way or even by a lighted match. H. Stockmeier states that in addition to the danger arising from accidental sparking from machinery starting the oxidation of the powder as a dust explosion, there is also a risk due to the production of hydrogen by the action of water on aluminium dust, *e.g.* in washing out the gum—the action begins at 30°, for it is not appreciable at 20°; and R. J. Zink suggested that the action of water on the small amount of aluminium carbide in aluminium produces inflammable hydrocarbons, thus 0·1 per cent. of aluminium carbide in 10 kgrms. of aluminium could give 4·8 litres of hydrogen. The subject has also been discussed by O. Edelmann, M. M. Richter, M. Bamberger and H. von Jüptner, O. Bauer, etc.

According to E. Kohn-Abrest, aluminium powder is not oxidized by eight days' heating in air at 100°, but oxidation can be detected after eight days' exposure to 175°. When aluminium powder is heated in a current of air, it begins to absorb oxygen at 400°; between 400° and 625°, the rate of absorption increases steadily and remains constant between 625° and 750°. At 800°, a further absorption of oxygen commences, which increases as the temp. is raised to 1000°, and then remains constant between 1000° and 1200°. When aluminium powder is heated during one hour at 1000°, or for the same period at temp. rising from 500° to 1050°, 59 per cent. of oxygen is absorbed, but no further absorption of oxygen occurs when the heating is continued for another two hours at 1000°. The product is a homogeneous pearl-grey powder, which decomposes hydrochloric acid with effervescence. It is pointed out that the formation of a suboxide AlO would require the absorption of nearly 59 per cent. of oxygen. H. Hinze found that amalgamated aluminium is rapidly oxidized in air, and aluminium which has been rubbed with mercury or a salt of mercury is quickly oxidized in air. When aluminium is allowed to stand on mercury covered with a thick film of oxide, H. F. Hunt and L. J. Steele found that, although no amalgamation is perceptible, the aluminium is rapidly converted into its hydroxide. The action is not so rapid when the metal is kept beneath dirty mercury, and is very slight when aluminium is floated on freshly distilled mercury. The action is most rapid with aluminium which has had its surface amalgamated. G. le Bon found that aluminium foil coated with a thin film of mercury is quickly oxidized by exposure to air, and a strip of the metal placed vertically in a vessel containing water and mercury is continuously corroded at its lower end until completely disintegrated. Since aluminium which has been pressed on moist platinum, silver, or tin behaves similarly, H. Hinze assumed that the increased oxidizability of aluminium is an electro-chemical effect, and is a good illustration of H. E. Armstrong's theory of chemical action. The phenomenon has also been studied by C. Jehn, P. Spica, C. Reichard, G. A. Maack, E. O. Erdmann, etc. —*vide infra*, aluminium amalgam. V. Zunino's analysis of the voluminous, grey, spongy mass formed when aluminium is immersed in mercury, and afterwards exposed to moist air, agrees with $Al_2O_3.5H_2O$, or $Al(OH)_3.H_2O$. J. H. Baille and C. Féry gave the composition $Al_2O(OH)_4$. P. R. Jourdain said that still more water is absorbed in a moist atm., and in a dry atm. or in vacuo at 200°, water is slowly lost, but the weight does not become constant even after several days. He also showed that some carbonate and peroxide are present in the product.

According to H. St. C. Deville,[3] **water** has no action on aluminium either at ordinary temp., at 100°, or at a red heat bordering on the m.p. of the metal. He said:

> I boiled a fine wire in water for half an hour and it lost not a particle in weight. The same wire was put in a glass-tube heated to redness by an alcohol lamp and traversed by a current of steam, but after several hours it had not lost its polish, and had the same weight. To obtain any sensible action it is necessary to operate at the highest heat of a reverberatory furnace—a white heat. Even then the oxidation is so feeble that it develops only in spots, producing almost inappreciable quantities of alumina. This slight alteration and the analogies of the metal allow us to admit that it decomposes water but feebly.

He added that the metal prepared by reducing cryolite with sodium is almost unavoidably contaminated with slag composed of the chlorides of sodium and aluminium; and when treated with water the aluminium chloride acts like an acid disengaging hydrogen. When the metal thus tarnishes in water, the presence of chlorides can be detected in the liquid. F. Wöhler, and R. Bunsen also found that the metal they prepared acted on water at 100°. H. St. C. Deville was not quite correct. According to W. Smith, there is a very slight action when aluminium powder and water are heated in a platinum dish to incipient boiling; but if heated in an ordinary test-tube, a vigorous evolution of hydrogen was observed. It is here assumed that the water dissolved a little alkali from the glass, and so attacked the metal. A. Liversidge found that commercial aluminium is attacked by rain-water, almost as readily as zinc is attacked. M. C. Schuyten showed that a drop of potassium permanganate soln. accelerates the decomposition by boiling water, but this is not the case with chlorates, perchlorates, or nitrates. J. H. Gladstone and A. Tribe also found that in the presence of a trace of iodine, of hydriodic acid, or of aluminium chloride, bromide, or iodide, or zinc chloride, aluminium decomposes water at ordinary temp. or at 100°. In all cases, hydrogen and aluminium hydroxide are formed. A. Ditte explained the action of water on aluminium by showing that the products of the reaction, hydrogen and alumina, deposit on the metal covering it with a thin protective film. If the conditions be such that the film is removed, the action becomes manifest. Boiling, for instance, removes the hydrogen, and if aluminium chloride, sulphate or nitrate be present in the water, the alumina may be removed, and the action goes on until a subsalt is formed which is sparingly soluble or insoluble. This covers the metal with a new protective film. L. Hugounenq found that purified aluminium is not attacked by purified water, but aluminium of commerce is attacked owing to the formation of local couples. C. Tissier said that the formation of the couple dispels the passivity of the aluminium. A. Scala, F. Schönfeld and G. Himmelfarb, and many others have studied the action of water on this metal. C. Matignon showed that aluminium powder is slowly attacked by water at 100°; and that the powder when ignited in air and plunged into steam, continues to burn with the evolution of hydrogen. H. J. Gladstone and A. Tribe showed that if aluminium be dipped in an acidified soln. of cupric sulphate or platinic chloride, and washed, it gives only a little hydrogen with water at 12°, but copious quantities are evolved at 100°. J. H. Baille and C. Féry found that amalgamated aluminium decomposes water at ordinary temp., and that the change is especially rapid with very thin sheets of metal amalgamated on the surface. G. le Bon, W. van Rijn, and P. Spica confirmed this observation. The aluminium foil is amalgamated by dipping it in an aq. soln. of mercuric chloride, and afterwards washing it in water. When a strip of aluminium is dipped in water containing a few drops of hydrochloric acid and a very small quantity of mercuric chloride, the formation of alumina can be observed in a few minutes, and the strip when removed from the liquid oxidizes very rapidly in air. The mercury-amalgam couple or, as J. Wislicenus called it, *excited or activated aluminium*, was shown by W. R. Ormandy and J. B. Cohen, and J. Wislicenus to be a valuable reducing agent, more active in some cases than the zinc-copper couple—*e.g.* in reducing nitrates and nitrites to ammonia. According to F. Mylius and F. Rose, if aluminium be immersed in water exposed to air, some hydrogen peroxide is formed. H. T. Barnes and G. W. Shearer inferred from the behaviour of aluminium electrodes that a film is formed over the surface of aluminium exposed to air or to water, and that the reaction in the case of water develops hydrogen peroxide. The development of hydrogen peroxide is dependent on the presence of dissolved oxygen; if air be absent, no hydrogen peroxide is formed. O. Ohmann[4] found that an intimate mixture of a gram of aluminium powder with 4·3 grms. of sodium peroxide is readily inflamed with a slight explosion by the addition of a few drops of water.

E. Heyn and O. Bauer found that aluminium undergoes two types of corrosion; it may corrode uniformly, forming a coating of oxide over the whole surface, or it may be attacked locally, forming blisters and exfoliations. The latter is the more dangerous in the industrial application of aluminium. They found that local pitting occurred with hard or cold-worked aluminium, and that tap-water produces a slight uniform corrosion after several months' exposure with soft or annealed sheet; and local corrosion, blistering, or disintegration with hard sheet. Distilled water did not cause blistering even with hard sheet. Local corrosion was attributed to (i) the initial stresses in hard sheet causing strains and buckling when released by corrosion; and to (ii) the electropositive character of hard- or cold-worked aluminium to the soft or annealed metal. This conclusion was confirmed by G. H. Bailey, and L. Guillet. E. Heyn and O. Bauer found the relative rates of corrosion of hard and soft sheet aluminium by distilled water exposed freely to air, to be respectively 45 and 54. The metal is not attacked by air, or water in the absence of air or oxygen; or, as G. H. Bailey expressed it, except in waters containing free acid or alkali, no aluminium is dissolved, and the corrosion is purely a question of oxidation of aluminium to alumina at the expense of the oxygen dissolved in the water. The greater the degree of purity of the water, the less the action. According to H. S. Rawdon and co-workers, failure occurs owing to the attack on the impurities which are found along the intercrystalline boundaries, but, on annealing after cold work, the impurities no longer coincide with the crystal boundaries, and corrosion is not truly intercrystalline in character. E. Heyn and O. Bauer, and G. H. Bailey found that the rate of attack is augmented by a rise of temp. Thus, at 20° and 70°, the relative rates of attack are 39 : 110. The silicon content of the aluminium, between 0·57 and 0·86 per cent., had no appreciable influence on the result; G. H. Bailey also found that when the proportion of silicon is higher than that of iron, the action is less pronounced in the case of water and acids, and more pronounced in salt soln.;

ie stated that the attack by aluminium is notably accentuated if the aluminium ;ontains sodium or copper. L. Guillet confirmed the conclusion with respect to ;opper. A. Barillé found that aluminium is slowly attacked by *seltzer water*, forming ı flocculent precipitate of aluminium hydroxide. A. Trillat studied the corrosion of aluminium in the liquids encountered in the brewing, milk, and cheese ndustries.

According to F. Wöhler, and H. St. C. Deville, soln. of **sodium or potassium hydroxide** act vigorously on aluminium, transforming it into alkali aluminate and setting free hydrogen. G. H. Bailey represented the speed of the reaction with two different samples of commercial metal and tap-water, N-H_2SO_4, N-HCl, and N-NaOH in terms of the number of grains per sq. yd. dissolved per day :

Tap-water	N-H_2SO_4	N-HCl	N-NaOH
0·80	10·0	35·5	708
0·85	7·7	29·8	898

J. W. Mallet found that the purified metal resists attack better than the commercial metal. J. W. Richards found the best commercial metal reacted with a cold dil. soln. of potassium hydroxide with one-seventh the rate of aluminium alloyed with 3 per cent. of copper, and with one-seventieth the rate of aluminium alloyed with 2 per cent. of copper and one per cent. of zinc. A. Stutzer found electrolytic aluminium is attacked more slowly than the metal made by the sodium process, and he attributed this to the presence of sodium in the latter, but J. W. Richards suggests that the truer explanation rests on the higher degree of purity of the electrolytic metal. A. Cavazzi said that the reaction is represented by $2Al+6MOH=2Al(OM)_3+3H_2$; the speed of the reaction increases with the temp. and conc. of the soln., but J. Bogusskv and J. Zaljesky found that the speed of soln. is not proportional to the conc. of the alkali. A. J. Hale and H. S. Foster studied the attack by hydroxide soln. A. Röhrig found the presence of sodium silicate inhibits the attack by the alkali-lye—*vide infra*. S. Kappel found that aluminium in contact with air and a soln of potassium hydroxide readily produces the nitrite, and in the cold, nitrates and hydrogen peroxide are formed. A boiling soln. of potassium or sodium ethoxide attacks aluminium only with the oxidation of the alcohol to form water. J. Czochralsky showed that the blackening of aluminium vessels with use is not directly dependent on the proportion of iron present as an impurity, but is rather dependent on the alkalinity of the water which comes in contact with the metal. A soln. of **calcium hydroxide,** or lime-water, also acts rapidly on aluminium, but the resulting calcium aluminate is insoluble in water, and is precipitated on the metal protecting if from further action. E. Beckmann found that a soln. of **barium hydroxide** rapidly dissolves aluminium until the soln. contains the molar proportion $Al_2O_3 : BaO$; the reaction is then slower and aluminium hydroxide begins to separate out ; with hot soln. barium aluminate is formed.

C. H. Crowe, and K. L. Meissner have studied the action of alkali chloride soln. on aluminium. A soln. of **sodium chloride** acts feebly on aluminium. This subject has been investigated by A. E. Hunt, J. W. Richards, G. H. Bailey, C. Tissier, A. Ditte, E. Donath, F. Zmerzlikar, E. Heyn and O. Bauer, and A. J. Hale and H. S. Foster. W. Smith found that hot conc. soln. of sodium chloride attack the metal with the evolution of hydrogen, and the soln. become alkaline ; it is assumed that in the presence of sodium chloride, the aluminium attacks the water setting free hydrogen, and the aluminium hydroxide so formed reacts with the sodium chloride, forming a basic aluminium chloride and sodium hydroxide. The action of a soln. of sodium chloride in the presence of an acid was found by A. E. Hunt, W. Smith, and A. Ditte to be greater than when either is alone. A. Ditte said that the attack by alkali halides is prevented by the formation of a protective film of aluminium hydroxide, and that the presence of the dil. acid dissolves the hydroxide, and enables the saline soln. to continue its action. The action is also faster near the surface because atm. oxygen plays a *rôle* in the reaction. He also showed that the *carbon dioxide plays a part analogous to that of acetic acid, and that the resultin sodium carbonate readily reacts with aluminium as indicated below. A. Ditte* als found that soln. of **potassium chloride, sodium and potassium bromides,** and **potassium iodide** act like soln. of sodium chloride. He represented the reaction b the equations: $6NaCl+2Al+6H_2O=2AlCl_3+6NaOH+3H_2+157{\cdot}3$ Cals.; an $3NaOH+AlCl_3=3NaCl+Al(OH)_3+28{\cdot}7$ Cals. The corrosive action of **sea-wate** was studied by A. E. Hunt, H. C. H. Carpenter and C. A. Edwards, etc. A. Ditt said that the action of sea-water is analogous to that of sodium chloride on aluminium; and that **calcium chloride** and **magnesium chloride** soln. act similarly; A. J. Hale and H. S. Foster, and C. H. Crowe examined the action of soln. o these salts.

According to C. Formenti and M. Levy, aluminium reacts with soln. of many **sulphates,** forming alums. According to W. Smith, when aluminium powder is heated to 100° in a platinum vessel with a soln. of **sodium nitrate** or **potassium nitrate,** there is a faint evolution of hydrogen, whereas in a soft glass vessel, there is a vigorous action, and an evolution of much gas. This is due to the presence of alkali developed by the action of the water on the glass. W. Smith assumes that the reaction is: $6Al+14H_2O+2NaNO_3=6Al(OH)_3+2NaOH+2NH_3+H_2$. The alkali derived from the glass and from the sodium nitrate continually increases so that there is an ever-increasing reducing action and finally there is a tempestuous evolution of hydrogen and ammonia. E. Donath, and F. Zmerzlikar studied the attack of aluminium by soln. of nitrates. W. R. E. Hodgkinson and A. H. Coote found that aluminium has no action on a soln. of **ammonium nitrate.** The action of ammonium salt soln. in producing brown films on aluminium was the subject of a patent by C. Göttig. A boiling soln. of **ammonium phosphate,** made faintly alkaline with ammonia, was found by W. Smith to be attacked with the formation of a white phosphate, and he assumes that the boiling soln. is decomposed into ammonia and phosphoric acid, and that the former, *in statu nascendi*, decomposes the water, forming aluminium hydroxide and hydrogen; the hydroxide and phosphoric acid produce aluminium phosphate. A hot soln. of **ammonium arsenate** acts on aluminium, forming a mixture of hydrogen, arsine, etc.

A. Cavazzi, and W. Smith found that when aluminium powder is boiled with a *N*-soln. of **sodium carbonate,** there is so copious an evolution of hydrogen and carbon dioxide that the soln. froths vigorously. The reaction is also vigorous with foil and sheet aluminium. It is assumed that the aluminium first reacts with the water, forming hydrogen and aluminium hydroxide, and the latter reacts with the sodium carbonate forming, sodium aluminate: $2Al+3H_2O+Na_2CO_3=2NaAlO_2+3H_2+CO_2$. Since a boiling soln. of sodium carbonate does not react with aluminium hydroxide, W. Smith makes the supplementary hypothesis that the reaction can occur in the presence of nascent hydroxide. A. Ditte said that the reaction between sodium carbonate and aluminium furnishes sodium aluminate and hydrocarbonate, and it ceases when all the carbonate is transformed into hydrocarbonate. A. J. Hale and H. S. Foster examined the action of sodium carbonate soln. R. Seligman and P. Williams showed that sodium silicate forms a coating of aluminium silicate on the metal, and prevents the attack by sodium carbonate used for cleaning aluminium.

C. Weltzien[5] found that aluminium is attacked by **hydrogen peroxide,** and O. Droste noted that an aluminium beaker containing a 3 per cent. soln. of hydrogen peroxide was quickly corroded. 99·46 per cent. aluminium with 0·03 per cent. of iron and 0·51 per cent. of silicon is rapidly dissolved with the exception of a few specks of silicon together with some adherent aluminium. A white precipitate of $Al(OH)_3.H_2O$, but no colloidal aluminium hydroxide, is formed. He added that aluminium vessels are not suited for liquids which contain or can form **oxygen** or **ozone.** The slow action of aluminium in decomposing hydrogen peroxide was attributed, by H. T. Barnes and G. W. Schearer, to the protective action of the surface film of oxide.

Aluminium is an active element, and under proper conditions reacts with many other elements, forming salts, etc. According to H. Moissan,[6] it is superficially attacked by **fluorine** at ordinary temp., and the thin layer of aluminium fluoride protects the metal from further attack; but at a red heat, the action is very energetic. C. Matignon said that aluminium burns vigorously in the halogens, the hydrogen halides, and the non-metallic halides. F. Wöhler noted the combustion of the metal in **chlorine**, but H. Gautier and G. Charpy found that liquid chlorine at its b.p. has no action, but at −20°, combination occurs with incandescence. G. H. Bailey said that the corrosive action of chlorine at ordinary temp. is negligibly small. According to E. R. Hodges, **bromine** vapour reacts with warm aluminium foil with brilliant incandescence. H. Gautier and G. Charpy found that with liquid bromine there is an energetic reaction at 15°, and a fragment of aluminium on liquid bromine becomes incandescent and runs about the surface of the liquid like potassium does on water. With bromine-water, there is a regular evolution of hydrogen, and after a time, some oxybromide separates. C. Friedel and L. Roux said that aluminium subbromide is formed if the aluminium be in excess. J. Nicklès found that bromine or **iodine** in dried ether reacts vigorously with aluminium, forming either the bromide or the iodide.

Gaseous **hydrogen chloride** readily attacks aluminium even at a low temp., but, according to J. B. Cohen, there is no action if the gas be thoroughly dried; nor, according to L. Kahlenberg and H. Schlundt, does a soln. of that gas in dried liquid hydrogen cyanide attack the metal. F. Stockhausen and L. Gattermann, and E. Kohn-Abrest found that powdered aluminium is not acted on by 2 hrs.' exposure to cold dry hydrogen chloride, but is rapidly attacked if previously heated in hydrogen to 300°; once the reaction has commenced, it continues without the application of more external heat—*vide* the preparation of aluminium chloride. Both F. Wöhler, and H. St. C. Deville noted the rapid dissolution of aluminium in **hydrochloric acid.** This acid is *le véritable dissolvant* of aluminium. The action is quicker with conc. than with dil. acid, and quicker hot than cold. A. J. Hale and H. S. Foster studied the action of hydrochloric acid; and F. and W. Mylius, the thermal changes in the attack of the metal by this acid. A. Sieverts and P. Lueg found that if the initial conc. of the acid be C milliequivalents per 20 c.c.; x c.c. the amount of hydrogen evolved at the time t; v_m c.c. denotes the vol. of a millimol of hydrogen under standard conditions; and B the vol. of hydrogen under standard conditions eq. to the initial quantity of metal, then, the velocity of the reaction $dx/dt=K(C-2x/v_m)(B-x)^4$. At 20°, they found the velocity constant, K, to be

Conc. of acid . .	$0·5N$	$0·67N$	N	$1·33N$	$1·67N$	$2N$
K	0·40	1 04	4·2	9·8	16·1	22·7

and that K is very nearly proportional to the 3rd power of the conc. of the acid. At 20° with N-acid, $K=4·2$, and at 30°, $K=5·65$. According to J. W. Mallet, the purified metal is not so readily attacked by solvents generally as is the impure metal. It is assumed that the galvanic action of local couples keeps the surface of the impure metal free from a protecting layer of gas. J. W. Richards said that the presence of silicon renders the metal particularly susceptible to rapid attack, and during the reaction some silicon escapes as hydride. This can be prevented by keeping an oxidizing agent like bromine in the acid. If the best commercial aluminium, and an alloy with 3 per cent. of nickel, be treated with 3 per cent. hydrochloric acid, the less pure metal dissolves 30 times as fast as the other. If a little hydrochloric acid be added to other acids, the metal is dissolved presumably as aluminium chloride, and the latter then reacts, forming a salt of the acid and reproducing hydrochloric acid. The catalytic action is thus cyclic. The accelerating influence of reducing agents—nitrobenzene, etc.—on the dissolution of metals in acids was discussed by H. J. Prins. A. Sieverts and P. Lueg found that there is a marked period of induction in the action of hydrochloric acid, and that the speed of dissolution is greatly inhibited by a number of alkaloids.

With N-acid, and 2·5 millimol of the following alkaloids per litre, the value of K was 4·30 with caffeine; 4·2, cocaine; 4·1, cinchonine; 2·44, morphine; 2·40, coniine; 2·13, quinine; 1·97, narcotine; 1·83, brucine; 1·80, codeine; 1·17, nicotine; 1·08, veratrine; and 1·03, β-naphthoquinoline.

The effect is due to the adsorption of the "poison" by the metal which renders the surface inactive. **Hydrobromic and hydriodic acids** react similarly to hydrochloric acid. R. Seligman and P. Williams found that $\frac{1}{2}N$-hydrobromic acid attacks aluminium with but half the velocity of $\frac{1}{2}N$-hydrochloric acid. G. H. Bailey made some observations on this subject. With **hydrofluoric acid,** the aluminium fluoride which is produced has a low solubility, so that a protective coating of the fluoride may remain on the metal when the conc. of the acid is great enough.

A. D. White found that **hypochlorous acid** attacks aluminium slowly, hydrogen is evolved and aluminium hydroxide is deposited, some chlorine is then formed; if an excess of aluminium be used, and the evolution of gas has ceased, the filtered soln. deposits aluminium hydroxide when carbon dioxide is passed therein. It is assumed that the soln. contains aluminium hypochlorite, and that the first product of attack by the acid is this salt and hydrogen; the aluminium is also slowly oxidized and hydrochloric acid is formed. The interaction of hypochlorous and hydrochloric acids gives chlorine; some oxygen appears in the gas evolved, and is due to the spontaneous decomposition of the hypochlorite. Aluminium is slowly attacked by a soln. of **calcium hypochlorite** (bleaching powder) and calcium aluminate is said to be a product of the action. D. Tommasi stated that only a trace of chloride was formed after aluminium had been in contact with **chloric acid** for six hours. W. S. Hendrixson found that aluminium slowly dissolves in cold dil. chloric acid, and whatever the conc., hydrogen is given off, and, as in the case of zinc, some acid is reduced, and some chloride is formed. The ratio of chlorate to chloride formed with N-acid is 1 : 7, and with $2N$-acid 1 : 5. The metal also becomes coated with aluminium oxide. D. Venditori found finely divided aluminium reduces chloric acid to hydrochloric acid in the presence of acids; **perchloric acid** is not affected. Acidified soln. of **chlorates** and **perchlorates** behave in an analogous manner. G. Gore found that with an aluminium-platinum couple in a soln. of **iodic acid,** the aluminium is strongly attacked.

A. Orlowsky [7] could detect no signs of a reaction in the cold between aluminium and **sulphur** or a soln. of sulphur in carbon disulphide. W. Spring said that under a press. of 6500 atm. the reaction between sulphur and aluminium is incomplete, although a polysulphide is formed. According to H. St. C. Deville, aluminium at a red heat does not react with sulphur vapour, but, at a "high temp. it combines directly with sulphur to give aluminium sulphide." According to H. Fonzes-Diaçon, and C. Matignon, a mixture of eq. proportions of precipitated sulphur and finely powdered aluminium can be ignited by burning magnesium, and aluminium sulphide is formed. A mixture of **selenium** and aluminium behaves in a similar manner. F. Wohler also obtained compounds of aluminium with selenium and **tellurium.** G. H. Bailey said that the corrosive action of **hydrogen sulphide** at ordinary temp. is negligibly small. According to H. St. C. Deville, hydrogen sulphide has no action on aluminium, and the same remark applies to an aq. soln. of hydrogen sulphide, or of **ammonium sulphide.** J. Margottet also said that hydrogen sulphide is without action on aluminium, but J. W. Richards noted that hydrogen sulphide is absorbed by the molten metal, and the metal then flows sluggishly; just before setting the gas is rejected "so actively that a crackling sound can be heard several feet away . . . at the same time, the sluggish metal becomes quite fluid." The gas entangled in the solidifying metal also produces cavities or blowholes. C. Matignon found that aluminium can be burnt in the vapour of **carbon disulphide,** forming carbon and aluminium sulphide but not carbide; he also burnt aluminium powder in **sulphur dioxide** producing the oxide and sulphide; G. H. Bailey found the corrosive action of sulphur dioxide at ordinary temp. is negligibly small. A. Cavazzi found that when a mixture of aluminium filings and sugar charcoal is heated in the vapour of carbon disulphide, a little aluminium sulphide is formed. Aluminium reacts with **sulphurous acid,** forming, according to P. Schweitzer, a mixture of aluminium sulphite, sulphate, trithionate, and thiosulphate. P. Degener said that sulphurous acid attacks the metal only in the presence of alkali chlorides. C. Matignon burnt aluminium in the vapour of **sulphur chloride.**

According to F. Wöhler, cold conc. **sulphuric acid** does not attack aluminium, but the hot acid dissolves it rapidly with the evolution of sulphur dioxide. H. St. C. Deville showed that sulphuric acid diluted in the proportion most suitable for attacking zinc has no action on aluminium, and the action is not assisted by contact with a foreign metal. He found that after several months' contact with dil. sulphuric acid, a slight action could be detected. H. E. Roscoe said conc. and dil. sulphuric acids have no action on aluminium. As a matter of fact, dil. and conc. sulphuric acids act very slowly on aluminium in the cold and more rapidly when hot. A. J. Hale and H. S. Foster studied the action of sulphuric acid on aluminium. According to R. Seligman, anhydrous sulphuric acid is without action on aluminium, whereas ordinary oil of vitriol is markedly corrosive. P. Pascal and co-workers found that aluminium is not seriously attacked by sulphuric acid over 98 per cent. P. B. Ganguly and B. C. Banerji found the action is most vigorous near the surface of the acid when an aluminium rod is partly immersed in the dil. acid. G. A. le Roy reduced the loss in weight suffered by plates of metal in sulphuric acid, to loss in grams per sq. metre in 12 hrs., and he found with purified and commercial aluminium at 15°–20°:

		1·842	1·711	1·580	1·263
Sp. gr. of acid		1·842	1·711	1·580	1·263
Loss	pure Al	18·40	24·50	19·00	4·60
	comm. Al	21·00	25·80		

and at 150°, with acid of sp. gr. 1·842, the losses were respectively 240 and 267. Hence, it is impracticable to use aluminium for pans, pumps, tank linings, etc., used in handling sulphuric acid. It will be observed that the attack on purified aluminium is slower than on the impure metal. A. Ditte found that cold 2·5 per cent. sulphuric acid at first acts very slowly, but after several hours, the air condensed on the surface of the metal is removed, and the metal slowly dissolves with the evolution of hydrogen. The hydrogen collects on the surface of the metal protecting it from further attack. J. M. Weeren gave a similar explanation with respect to zinc. Any agent which breaks up or removes this gaseous film, hastens the attack by the acid. Soln. of many metal chlorides reduced by aluminium behave in this way; for instance, the addition of a few drops of platinum chloride to the acid leads to the deposition of platinum on the aluminium, the surface is roughened, the gas escapes quicker, and the solvent action is more rapid. Gold, mercury, and copper chlorides act similarly; zinc and iron chlorides have no such stimulating action. The rate of attack by the cold acid gradually slows down because of the deposition of an undissolved basic sulphate, $3Al_2SO_4.Al_2(SO_4)_3.18H_2O$, on the metal protecting it from the acid. Even very dil. sulphuric attacks aluminium if the metal is prevented from being covered with the film of gas—*e.g.* by boiling. It is probable that the metals deposited on the aluminium, as also the impurities in the aluminium, act as electronegative elements to the electropositive aluminium; local couples are formed, and the gas is disengaged from the electronegative element, not the aluminium. A. Ditte, and F. Winteler mention the separation of sulphur during the action of conc. sulphuric acid on aluminium, but W. Smith detected no such formation of sulphur. According to M. G. Levi and co-workers, aluminium rapidly dissolves in aq. soln. of **potassium persulphate** without the development of gas; with **ammonium persulphate** the dissolution is slower. G. A. Maack produced selenium and tellurium respectively from aq. soln. of **selenous and tellurous acids** by aluminium.

Melted aluminium was shown by F. Briegleb and A. Geuther[8] to absorb **nitrogen,** and J. W. Mallet prepared a nitride (*q.v.*); some nitride is formed when aluminium is burnt in air. Gaseous **ammonia** does not act on the metal at ordinary temp., but at 700°, A. H. White and L. Kirschbraun found that the nitride is formed. G. G. Henderson and J. C. Galletly heated aluminium in a stream of ammonia and obtained only a small proportion of nitride. F. Wöhler found that aqua ammonia acts slowly on the metal, producing a little alumina, part of which dissolves. A. J. Hale and H. S. Foster studied the action of aq. ammonia on aluminium. W. Smith found that a hot conc. soln. of ammonia generates hydrogen and forms aluminium hydroxide. A. Ditte said that the action with aq. ammonia continues so long as the aluminate dissolves in the excess of alkali, and stops as soon as a film of aluminate forms on the metal. S. Kappel said that aq. ammonia in contact with air and aluminium forms nitrites. C. Göttig, and A. Ditte mention that a yellow to brown layer of the unattacked impurities remains on the surface after treatment with ammonia. According to T. Curtius and J. Rissom, **hydrazoic acid,** HN_3, attacks aluminium a little, forming aluminium hydroxide, not the azide. According to C. Matignon, aluminium powder can burn in **nitrous oxide, nitric oxide,** and **nitrogen peroxide,** forming alumina and the nitride. P. Sabatier said that aluminium filings are not attacked when heated in nitric oxide, and that nitrogen peroxide is without action at 500°. E. Müller and H. Barck found the action of nitric oxide was only slight below 600°; at 600°, 8 per cent. was decomposed. J. J. Sudborough found **nitrosyl chloride** attacks aluminium in the cold. F. W. Bergstrom found that **sodium amide,** or a soln. of sodium in liquid ammonia, reacts with amalgamated aluminium, forming *sodium amidoaluminate*, $Na[Al(NH_2)_4]$; **potassium amide** acts similarly, forming *potassium amidoaluminate*, $K[Al(NH_2)_4]$.

According to H. St. C. Deville, and F. Wöhler, dil. or conc. **nitric acid** has no action on aluminium at ordinary temp., and the former said that good results were obtained by substituting aluminium for platinum in Grove's battery. W. Smith noted that with hot nitric acid, at the b.p., nitrous fumes are evolved, but the action ceases when cooled below 50°. According to A. Ditte, the action of nitric acid resembles that of sulphuric acid in that cold 3 per cent. acid acts very slowly, but cold 6 per cent. acid acts more quickly. When the plate of metal has become rough or matte by the action, the gas escapes more freely from the surface, and the action is faster. The gas contains no hydrogen, and is mainly nitrogen and nitric oxide; a little ammonium nitrate is formed. The reaction does not stop with the formation of the neutral nitrate, for a white sparingly soluble basic salt, $5Al_2O_3.2Al(NO_3)_3.30H_2O$, is deposited. According to T. B. Stillmann, nitric acid of sp. gr. 1·15 attacks aluminium turnings more readily than an acid of sp. gr. 1·45; and with an acid of sp. gr. 1·35, the salt $Al(NO_3)_3.9H_2O$ is deposited. C. M. van Deventer found that 20–25 per cent. nitric acid attacks aluminium slowly at 25°-30°; the main reaction is $Al+4HNO_3 \quad Al(NO_3)_3+NO+2H_2O$, a little nitrogen and some ammonia are also formed. A. Ditte found that with 3 per cent. nitric acid mixed with a little platinum chloride, very little gas is produced, but much ammonium nitrate is formed; and E. Divers and T. Haga found that hydroxylamine is produced when nitric acid, mixed with a little hydrochloric acid, acts on aluminium, and that the reaction is independent of the aluminium chloride in the soln. The action of nitric acid on aluminium has also been studied by R. Woy, J. W. Richards, H. E. Roscoe, A. Quartaroli, A. J. Hale and H. S. Foster, G. Lunge and E. Schmid, and G. A. le Roy. In general, cold dil. and conc. nitric acid attacks platinum very slowly, for the metal becomes passive under the action of this acid. The conc. acid attacks aluminium violently at 100°. P. Pascal and co-workers found that the presence of sulphuric acid facilitates the action of nitric acid on aluminium, and the presence of ammonium nitrate also favours the attack; but nitric acid alone at any conc. does not seriously attack the metal. J. W. Mallet found that purified aluminium is not so readily attacked as the impure metal.

R. Seligman and P. Williams have overhauled the various statements regarding the effect of nitric acid and found that the most important condition affecting the rate of dissolution of aluminium in nitric acid is temp., Fig. 29. Over a considerable range of temp. an increase of 10° C. is sufficient to increase the rate of dissolution by 100 per cent. The practical importance of this factor, to which no reference has heretofore been made, is very great. The life of aluminium vessels used for the storage or transport of nitric acid can be greatly increased where it is possible to keep the temp. down. Next to temp., conc. plays the most prominent part in determining the rate of dissolution of aluminium in nitric acid, Fig. 29. The most active solvents are mixtures containing between 20 per cent. and 40 per cent. by volume of nitric acid of 1·42 sp. gr., whilst on the other hand some acids made from atmospheric nitrogen, and containing 94·7 per cent. of true nitric acid, were found to be almost without effect on aluminium. A sample of the metal suspended in this acid for 71 days lost only 0·0004 grm., eq. to a rate of dissolution of 0·015 mgrm. of aluminium per 100 sq. cm. per 24 hours. The extreme inactivity of acid of this strength is held to account for the great success which has attended the use of aluminium transport vessels by the Norwegian makers of nitric acid. Contrary to the statement made by A. Trillat, the presence of up to 0·05 per cent. chlorine in nitric acid was not found to affect the rate of attack of the latter upon aluminium. Similarly, no acceleration could be noted on the addition of up to 0·01 per cent. of iodine. On the other hand, the presence of traces of sulphuric acid was found to promote the rate of attack, 0·04 per cent. of sulphuric acid being sufficient to raise the rate of dissolution from 36 to 62 mgrms. per 100 sq. cms. per 24 hrs. The rate of attack is increased by the presence of the lower oxides of nitrogen. If the acid be kept free from such lower oxides the rate of attack on aluminium can be reduced considerably. The effect of the oxides of nitrogen produced by the interaction of nitric acid and aluminium in stimulating the attack is held to account for the fact often observed in practice that dissolution is most rapid in crevices or corners where the acid cannot circulate freely and where such products therefore accumulate. The effect of the physical state of the aluminium is considerable, the metal being attacked very much more readily when amorphous than when crystalline. The observation has been made that a partial change to the more resistant form is brought about by exposure for a few hours to a temp. of 125°, but that by a longer exposure to this temp. the metal loses its comparative immunity from attack. A similar change to the more resistant form has been observed to commence at a temp. as low as 100°. Moreover, it has also been noticed that metal which has been freshly annealed at 540° is more resistant to attack than metal which has been allowed to stand for about ten days after annealing. The composition of the metal is of very much smaller importance than has heretofore been assumed to be the case. Nevertheless, the purer metal is generally the most resistant to the attack of nitric acid. The statement by O. Guttmann that a mixture of nitric and sulphuric acids attacks aluminium less readily than the acids alone is erroneous. The attack by nitric acid on aluminium of high quality is quite uniform and no instance of local action or pitting was observed.

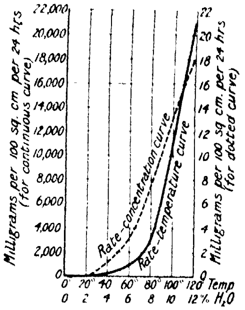

FIG. 29.—Effect of Temperature and Concentration on the Rate of Dissolution of Aluminium in Nitric Acid.

H. Fonzes-Diacon, and C. Matignon prepared aluminium phosphide by igniting with a piece of magnesium wire a mixture of red **phosphorus** and aluminium; L. Losana studied the action of less than 0·1 per cent. of phosphorus on the properties of aluminium. H. Fonzes-Diacon and C. Matignon showed that a heated mixture of **arsenic** and aluminium gave the arsenide; and the antimonide was obtained from a mixture of aluminium, **antimony**, and sodium peroxide. Q. A. Mansuri found that with arsenic a compound Al_3As_2, *aluminium ditritarsenide*, is formed. B. Reinitzer and H. Goldschmidt found **phosphoryl chloride** acts on aluminium similarly to what it does on magnesium and zinc, forming phosphorus trichloride, *aluminium metaphosphate and chloride, phosphoric* anhydride, pyrophosphoryl *chloride, and a little phosphorus suboxide; H.* Goldschmidt represented the action of **phosphorus pentachloride** on aluminium, $2Al+3PCl_5=2AlCl_3+3PCl_3$. *C. Matignon found that aluminium powder burns in the vapours of phosphorus,* **antimony and arsenic chlorides.** According to G. A. Maack, an aq. soln. of **arsenious oxide** *is not changed by aluminium; an acid soln. gives arsenic and arsine; and an alkaline soln., arsenic—for ammonium arsenate, vide supra.* According to *O. Ruff and K. Staib, with* **arsenic trichloride,** *the reaction is symbolized:* $3AsCl_3+3Al=2AlCl_3+AlAs_3Cl_3$. Antimony is immediately precipitated from a soln. of an **alkali antimonite**; with a hydrochloric acid soln. of **antimony trichloride,** stibine is evolved; and an aq. soln. of **potassium antimony tartrate** is not decomposed. Dil. or conc. **phosphoric acid** attacks aluminium with the development of hydrogen—F. Winteler said with the separation of phosphorus, but W. Smith denied this.

For the action of aluminium on **boron,** *vide* aluminium boride. H. Moissan[9] found that aluminium reacts with **boron sulphide** at a red heat forming aluminium sulphide and boride. A. Lubbert and M. Roscher found that aluminium foil 0·001 in. thick is dissolved in 4 days by a 4 per cent. soln. of **boric acid**; and G. Lunge and E. Schmid found that a similar soln. dissolved 29·5 mgrms. of sheet aluminium per sq. metre per day at ordinary temp. C. and A. Tissier, H. St. C. Deville, and G. H. Bailey found the corrosive action of soln. of boric acid is negligibly small. F. Wöhler found that melted **borates** are reduced to boron by aluminium at a high temp. H. St. C. Deville showed that if aluminium be melted under borax, some aluminium borate is formed. Hence borate slags rapidly corrode the metal. H. St. C. Deville, and J. W. Mallet noted that aluminium unites with **carbon**; and H. Moissan obtained a carbide by heating aluminium powder with lampblack. J. W. Mallet, and L. Franck found that **carbon monoxide** is reduced by heated aluminium, forming alumina and carbon—A. Guntz and A. Masson said aluminium carbide is formed at the same time: $6Al+3CO=Al_4C_3+Al_2O_3$. G. H. Bailey said the corrosive action of carbon monoxide or dioxide at ordinary temp. is negligibly small. At ordinary temp., N. Wender also found dry **carbon dioxide** to be without action on aluminium, and with the moist gas the action is *ganz unbedeutend*. L. Franck represented the reaction with dry carbon dioxide, $4Al+3CO_2=2Al_2O_3+3C$. K. Brunner found that aluminium powder burns vigorously when heated in an atm. of carbon dioxide, and graphitic carbon is formed. According to A. Guntz and A. Masson, the action is greatly accelerated if a little iodine or aluminium chloride or iodide vapour be mixed with the carbon monoxide or dioxide. According to A. Brochet and J. Petit, aluminium is rapidly attacked by soln. of **potassium cyanide** even in the cold. For the action of **carbonyl chloride**—*vide* aluminium chloride. L. Hugounenq found that 92 per cent. **alcohol** attacks aluminium even less than does water; the attack is accelerated in contact with other metals—very little by cadmium; more by chromium or cobalt; still more by platinum, tin, gold, silver, brass, and mercury; and quickest of all by copper, lead, bismuth, iron, zinc, and nickel. According to R. Seligman and P. Williams, dry fatty acids—*e.g.* a mixture of stearic, palmitic, and oleic acids—dry alcohols—*e.g.* methyl, ethyl, butyl, amyl, and benzyl alcohols—and dry phenol, cresol, and α- and β-naphthols rapidly attack aluminium at the b.p. of the organic compound, but if a small amount of water be present, the reaction is inhibited, or if it has already commenced, it is at once inhibited. It is assumed that the metal is normally protected by the film which covers it, but this film breaks down when exposed to the attack of the dehydrated substances considered. The presence of even the minutest traces of water is sufficient to inhibit the attack, owing either to the fact that the salts, peroxides, or alkyloxides, as the case may be, are immediately decomposed by water, aluminium hydroxide being formed, or because the aluminium exposed by the breakdown of the film is immediately reoxidized by water. G. Lunge and E. Schmid investigated the effect of various alcoholic liquids on aluminium—with 50 per cent. alcohol, the rate of dissolution is 10·2 milligrams per sq. metre per day. C. Matignon also burnt aluminium powder in carbon monoxide and dioxide; he also found that aluminium burns in the vapour of **formic acid,** $3HCOOH+4Al=2Al_2O_3+3H_2+3C$. R. Seligman and P. Williams found that a 77 per cent. aq. soln. rapidly attacks aluminium, and a crystalline formate is produced. A. Lubbert and M. Roscher found that aluminium foil 0·001 in. thick was completely dissolved by four days' immersion in 1, 5, and 10 per cent. soln. of formic and acetic acids; but results with foil do not represent the corrosion of heavier sheet metal, and G. Lunge and E. Schmid found that 1 and 5 per cent. soln. of acetic acid dissolved respectively 73·0 and 64·2 mgrms. of aluminium per sq. metre per day at ordinary temp. According to C. Matignon, aluminium does not burn in the vapour of **acetic acid.** H. St. C. Deville said that the action of acetic acid, diluted to the conc of the strongest vinegar, on aluminium is inappreciable or is extremely slow. A. Ditte assumed that if the protective film of hydrogen be removed by mechanical means, or if the action takes place in vacuo, aluminium is readily dissolved by acetic acid. F. Heeren found that acetic acid dissolves aluminium in the cold, more rapidly when heated, and hydrogen is evolved. W. Smith found that the solvent action is small, and, as H. St. C. Deville also showed, the action is much hastened if a little sodium chloride be present. According to R. Seligman and P. Williams, the rates of soln. of acetic acid of different conc. expressed in mgrms. of aluminium dissolved per 100 sq cms. in 24 hrs. at boiling temp., are:

Per cent. acid . .	99·9	90	80	60	40	20	5	1	0·2
Rate soln . .	7	165	295	410	533	582	610	1200	770

The attack by cold acetic acid is small, and the rate of dissolution increases with increasing dilution until the acid has a conc. of one per cent.; they found that with cold acid (20°):

Per cent. acid . .	99·2	98	90	70	25	10	2·5	1	0·5
Rate soln . .	0·00	0·01	0·26	0·60	0·65	0·90	0·85	1·100	1·4

and with the cold acid of still lower conc., the rate of soln. rose to a maximum 3·20 with 0·02 per cent. acid; and fell to 1·00 with 0·001 per cent. acid. The immunity of aluminium to ordinary conc. acetic acid is explained by the formation of a continuous film of an insoluble gelatinous basic acetate or oxide on the surface of the metal. The attack with the boiling acid is uniform; local action has been observed with the cold acid, and is produced by oxygen. With cold acid, too, the presence of oxygen promotes the reaction, for the speed is reduced to less than half if the oxygen atm. be replaced by one of hydrogen; with acetic acid of higher conc., the presence of oxygen was found to exert a retarding influence on the rate of dissolution. At the boiling temp., the oxygen is rapidly removed in the course of ebullition. While the rate of action with the 99 per cent. acid is but one-tenth that of the 90 per cent. acid, extraordinary to relate, the removal of the last trace of water from acetic acid raises the speed a hundred-fold; and conversely, the addition of 0·05 per cent. of water to a corrosive acid stops the action.

A. Ditte, and P. Degener found that acetic acid first forms a layer of hydrogen on the metal, and later on, a layer of hydroxide is formed. This is dissolved if an alkali or alkaline earth halide be present, and hence those salts hasten the attack. E. R. Hodges made some observations on the solubility of acetic acid, and showed that in the presence of hydrogen peroxide the activity of the acid is greatly augmented. He added that air or oxygen is necessary for the reaction, showing that the oxidation of the metal must precede the production of the acetate. M. Balland found that the action of vinegar is so slight as not to prevent the use of aluminium for cooking vessels. R. Seligman and P. Williams also found that with dil. acetic acid of about 10 per cent. conc., the addition of up to 1 per cent. of sodium chloride, potassium bromide, potassium iodide, or potassium nitrate has practically no effect in the case of boiling acid, whereas an eq. amount of sodium sulphate raises the rate of dissolution appreciably. In cold 10 per cent. acetic acid, however, 1 per cent. of sodium chloride is sufficient to raise the rate of dissolution tenfold, whereas potassium bromide effects a much smaller increase in the rate of attack, and potassium iodide and potassium nitrate none at all. 0·5 per cent. of sulphuric acid in the form of sodium sulphate raises the rate of dissolution fourfold in the case of dil. acid at normal temp. With acids of about 80 per cent. conc. in the cold, 1 per cent. of sodium chloride was found to raise the rate of dissolution from 3·6 to 270 mgrms. of aluminium dissolved per hundred sq. cms. per 24 hours. The same amounts of potassium bromide and potassium iodide increase the rate of dissolution approximately tenfold, but 0·5 per cent. of sulphuric acid in the form of sodium sulphate cannot be said to have any effect on the rate of attack by 80 per cent. acid in the cold, and potassium nitrate reduces the rate of dissolution to one-fourth of its previous value. The most serious effect of the addition of the substances experimented with was noted in the case of 80 per cent. acid at b.p. Here the rate of dissolution is raised by 1 per cent. of sodium chloride from 290 to 16,000. By 1 per cent. of potassium bromide the rate is only increased from 290 to 485, whilst potassium iodide and potassium nitrate may be said to have no effect; 0·5 per cent. of sulphuric acid in the form of sodium sulphate somewhat increases the rate of dissolution. The effect of the addition of chlorides to acetic acid is far greater than that of the addition of bromides or iodides. This is due to the greater activity of the liberated acid. Potassium iodide has very little effect with hot acetic acid, but with the cold acid, the attack depends on the liberation of iodine. If the iodine be removed, the rate of attack falls to that of the acid alone; with the boiling acid the iodine is volatilized.

R. Seligman and P. Williams found that the action of conc. **propionic acid**, and of **butyric acid** is entirely analogous to that of acetic acid. T. H. Eastorfield and C. M. Taylor found that above 300°, aluminium is attacked by **stearic acid** producing the corresponding ketone, stearone, by the aluminium stearate originally formed. R. Seligman and P. Williams found that with a mixture of 55 per cent. **palmitic acid**, 40 per cent. stearic acid, and 5 per cent. **oleic acid**, no action occurred when heated for 6 hrs. below 270°, but the metal was attacked occasionally at temp. between 270° and 300°. Above 300°, attack invariably took place and, once started, continued if the heating were stopped until the temp. had fallen as low as 100°. The form of attack is very similar to that of butyric acid, although far more rapid. When the acid was heated in a current of dry hydrogen, it was found that the attack started as low as 200°.

A. Lubbert and M. Roscher found that 10 per cent. soln. of palmitic acid, or stearic acid, or pure oleic acid dissolve aluminium foil 0·001 in. thick in 4 days. They also obtained similar results with 1, 5, and 10 per cent. soln. of **lactic acid, tartaric acid, citric acid,** and **phenol.** E. R. Hodges said that a cold conc. soln. of tartaric or citric acid does not attack aluminium. G. Lunge and E. Schmid found a 5 per cent. soln. of lactic acid dissolves from sheet aluminium 79·5 mgrms. of aluminium per sq. metre per day at ordinary temp., and that with 1 and 5 per cent soln. of tartaric and citric acids, and phenol the amounts dissolved are respectively 43·0 and 28·2, 31·7 and 35·8, and 8·2 and 3·8; while with a 0·25 per cent. soln. of **salicylic acid**, 105·8 is dissolved. A. Ditte made similar observations with respect to citric, oxalic, tartaric, and other acids as those he made with acetic acid. A. Lubbert and M. Roscher found that thin aluminium foil, 0·001 in. thick, is dissolved by two days' immersion in a 2 per cent. soln. of **gallic acid**, or in 1, 5, and 10 per cent. soln. of **oxalic acid.** E. E. Mathieu-Plessy found an aq. soln. of oxalic acid attacks aluminium at 200°. E. R. Hodges found that a cold sat. soln. of oxalic acid attacks aluminium slowly, while a hot soln. acts more quickly; the speed slackens at 57°, and below 30° the action is very slow. A. Ditte also studied the effect of oxalic, tartaric and citric acids, and found that the metal is attacked at the first moment of contact which covers the surface of the metal with a layer of hydrogen, and that later on the metal is covered with a film of hydroxide which is gradually dissolved if alkali or alkaline earth halides be present, and hence these salts hasten the attack. R. Degener obtained similar results. A. Benedicenti and S. Rebello-Alves found that aluminium combines with *protein* compounds when the two are shaken together. A. Lubbert and M. Roscher studied the action of red and white *wines*, *coffee*, and *tea*; M. Balland, wine, *beer*, *cider*, coffee, *milk*, *oil*, *butter*, *fat*, *urine*, *saliva*, and *damp earth*; G. Rupp, various kinds of liquid and solid foods; and G. Lunge and E. Schmid, *claret*, *hock*, *brandy*, beer, tea, and coffee. The latter said the action of coffee, tea, and beer is practically zero. D. Klein and A. Berg said that aluminium is not attacked by soln. of *sugar*. K. W. Charitschkoff found that aluminium is superior to copper, and equal to iron, in its power of resisting the action of *petroleum* products. J. W. Richards [10] made some observations on the corrosive effects of organic secretions, saliva, and perspiration.

Numerous other observations have been reported on the action of food stuffs, etc., on aluminium cooking and domestic utensils. The general results show that only small traces are dissolved, and, as G. Lunge and R. E. Schmidt said: "There is no danger of any injurious effect on the human body seeing that the food itself contains much more than is dissolved, in fact they could not act injuriously unless quantities hundreds of times larger were regularly entering the stomach." H. St. C. Deville[11] also said that the possible compounds which aluminium can form with the materials used *dans la cuisine sont d'une innocuité absolue*. The *Lancet* (1913) also concluded that "any suspicion that aluminium may communicate poisonous qualities to food in the process of cooking may be safely dismissed." The dark stains sometimes produced on aluminium were found by C. K. Tinkler and H. Masters to be produced by a ferruginous impurity.

According to E. Vigouroux, **silicon** does not unite with aluminium when the two elements are heated together, but if a third element be present a mixed silicide is formed (*q.v.*); F. E. Weston and H. R. Ellis could not make the silicide by heating aluminium powder with **silica**; in all cases silicon is formed. According to E. Vigouroux, the reduction occurs at 800°. C. Friedel and L. Roux found that **silicon tetrachloride** acts on aluminium at a red heat, forming free silicon and aluminium chloride. By treating **sodium fluosilicate** with an excess of aluminium, A. Pacz made silicon-aluminium alloys, and by replacing silicon in the complex fluoride by boron, beryllium, scandium, lanthanium, zirconium, iron, cobalt, nickel, copper, and vanadium, corresponding alloys were formed. G. Rauter said the reaction begins at 360°–370°. E. Kohn-Abrest found that when aluminium is heated in a **porcelain** boat at 1100° in vacuo, a yellow film of aluminium silicide is formed. Aluminium vapour attacks porcelain liberating silicon, which is absorbed by the molten aluminium. Molten aluminium was found by D. P. Smith to blacken **glass.** A. L. Williams found that, unlike copper, aluminium did not frit with fused **mica.** C. and A. Tissier, H. St. C. Deville, and F. Wöhler found that glass and **silicates** generally are reduced to silicon by molten aluminium at a high temp. Hence silicate slags rapidly corrode the metal. If the metal be melted in **fireclay** there is a risk of contamination; the silicate in the best plumbago crucibles was found by J. W. Richards to increase the percentage of silicon in aluminium melted therein. H. St. C. Deville found that if aluminium be melted in a glass vessel an alloy of silicon and aluminium, and an alkali aluminate are formed. Magnesia-lined crucibles or furnace beds can be used satisfactorily for melting aluminium.

As indicated above, an aq. soln. of the **alkali hydroxides** is a very active solvent for aluminium; but H. St. C. Deville showed that these remarks do not apply to the fused hydroxide, which does not attack aluminium; he said: "A bead of the pure metal may be dropped into melted sodium hydroxide, contained in a silver vessel, at a red heat, without observing the least disengagement of hydrogen." A. Cavazzi also showed that aluminium is not in the least affected by fused alkali hydroxide provided no extraneous water is present. According to N. N. Beketoff, aluminium reacts with potassium hydroxide at high temp.; some potassium is formed and volatilized. A. Rossel and L. Frank found that when a mixture of **sodium dioxide** and aluminium powder is exposed to damp air, moisture is absorbed and spontaneous inflammation ensues; if the mixture be moistened, a very high temp. is produced. The mixture is dangerous and requires handling with care. According to J. W. Mallet, **calcium, strontium, and barium oxides** are partly reduced at a high temp. by aluminium and the reduced metals are volatilized. N. N. Beketoff obtained alloys of aluminium with up to 33 per cent. barium by heating baryta with an excess of aluminium. J. H. T. Aumann found that **magnesium oxide** is also partially reduced by aluminium. F. E. Weston and H. R. Ellis found that aluminium reduces lime when heat is supplied, and that magnesia is not reduced. Both calcium and magnesium reduce alumina when the mixture is ignited with a fuse.

C. and A. Tissier[12] first noted the reduction of the **metal oxides** by aluminium; they did not succeed in reducing zinc or manganese oxide in this way; but they reduced iron oxide, forming an iron-aluminium alloy; there was a strong explosion with copper oxide, and with lead oxide, 50 grms., and aluminium foil, 2·9 grms., the crucible was broken to pieces and the doors of the furnace blown off. Aluminium oxide has a very high heat of formation—about 131·2 Cals., and this is equal to or slightly lower than the heats of formation of the oxides of calcium, strontium, lithium, and magnesium, but larger than the heats of formation of sodium, potassium, rubidium, silicon, boron, and most of the other metal oxides. Hence, unless these magnitudes alter adversely with rise of temp. it would be anticipated that *aluminium would reduce the metal oxides at high temp.* Some such hypothesis guided H. Goldschmidt, who found that the oxides of the alkalies and alkaline earths are reduced with difficulty by aluminium, but practically all the other metal oxides are reduced by heating them with aluminium powder, and he obtained either the metal, or an alloy of the metal, with aluminium, from the oxides of chromium, manganese, iron, copper, titanium, boron, tungsten, molybdenum, nickel, cobalt, zirconium, vanadium, niobium, tantalum, cerium, thorium, barium, calcium, sodium, potassium, lead, and tin. He said :

> In a thermite reaction, a metallic compound is reduced by one of several metals or metallic alloys in such a way that when the mixture is ignited at one place, the reaction continues of its own accord, so that under complete oxidation of the reducing element, a fluid slag is formed, while the reduced metal is obtained as a homogeneous uniform regulus ; if the oxide is used in excess, the reduced metal is free, or practically free, from the element used as a reducing agent.

The solid oxide is intimately mixed with rather less than an eq. quantity of granulated aluminium, and is placed in a crucible lined with magnesia. Owing to the high ignition temp. of the mixture, the reaction is started either by burning magnesium, or by the aid of a special ignition powder—a mixture of barium dioxide and aluminium—which is placed on top of the mixture of oxide and aluminium, and lighted with a match. When the reaction has been started in one spot it is propagated throughout the mass with great rapidity. So much heat is generated that the reduced metal is melted. Reductions of this type are called **thermite reactions,** or **aluminothermic reactions.** In these reactions the heat is developed with great rapidity, and the local rise of temp. is very great—estimated in some cases to be 3000° in 60 secs. The system may be likened to a furnace from which gaseous products are not evolved, and in which metals themselves are used as fuel. The process is employed for the production of carbon-free metals or alloys like chromium, manganese, molybdenum, ferro-titanium, ferro-vanadium, ferro-boron, cupro-manganese, etc. A mixture of finely divided aluminium with ferric oxide (or the oxide of some other metal), approximating to $2Al + Fe_2O_3$, is sold under the registered name *thermit*, and it is used in joining or welding iron and steel rails, pipes, etc., and in repairing fractured parts of machinery—engine frames, crank-shafts, etc. The process has been described by W. H. Wahl, E. Stütz, etc. A suitable mould is fitted round the part to be repaired, and molten iron produced by the thermit reaction is allowed to flow into the place where the joint is to be made. A. Colani, C. Matignon, R. Trannoy, and H. Fonzes-Diacon prepared phosphides, arsenides, silicides, and borides by simultaneously reducing two oxides by the thermite reaction. H. Moissan, E. Wedekind, A. Stavenhagen and E. Schuchard, etc., have prepared aluminium alloys by this process. W. H. Greene and W. H. Wahl dissolved the metal oxide in cryolite and reduced it to the metal by means of aluminium.

H. Goldschmidt also showed that other compounds can be reduced by aluminium powder—for example, the **metal sulphides** are more easily reduced than the oxides, as might be anticipated from the smaller heat of formation. The heats of formation of zinc, magnesium, manganese, potassium, sodium, strontium, and calcium sulphides are greater than this, cadmium, iron, etc., less. H. Ditz examined the process with iron sulphides. The **metal sulphates** react more vigorously than the sulphides, and C. Matignon said that mixtures of the sulphates and aluminium powder are often more explosive than with the nitrates. C. and A. Tissier, for instance, found that a violent explosion occurs when potassium and sodium sulphates are melted with aluminium. A. Rossel and L. Frank found that the reduction of **barium**

sulphate and of **calcium sulphate** is attended by a violent explosion; some sulphur is formed. F. Faktor reduced **sodium thiosulphate** by heating it with aluminium, and obtained aluminium sulphide. C. Matignon found that the **metal chlorides** are not suitable for reduction by aluminium on account of their volatility. A. Rossel and L. Frank reduced sodium chloride with aluminium, and they obtained some chlorine in the reaction with chromic chloride. The Chemische Fabrik Griesheim Elektron reduced **potassium fluoride** with aluminium: $6KF+Al=3K+K_3AlF_6$. According to J. W. Richards, when **fluorspar** is melted it gives off a little hydrofluoric acid vapour, produced by a reaction with the hygroscopic moisture, this forms a little aluminium fluoride; otherwise, the molten fluoride has no action on aluminium. He also stated that **cryolite** attacks finely divided aluminium at a temp. exceeding 1100° with the possible formation of a subfluoride; but the metal *en masse* is not attacked. When aluminium powder is fused with **silver chloride,** a silver-aluminium alloy is formed, and when the vapour of **mercurous chloride** is passed over heated aluminium, mercury and aluminium chloride are volatilized, and the aluminium is melted by the heat of the reaction. C. and A. Tissier found that **potassium carbonate** is less vigorously reduced by aluminium than the sulphate, some carbon and alkali aluminate being formed. There was no deflagration. According to J. W. Mallet, if a mixture of aluminium and dry **sodium carbonate** be heated in a carbon or lime crucible, or in a graphite crucible lined with lampblack, sodium is formed and volatilized, and there remains a regulus of aluminium, crystals of alumina, aluminium nitride, and carbon It is assumed that carbon is separated and sodium aluminate is first formed, and the latter is then reduced by more aluminium. The corrosion and pitting of aluminium when cleaned with soda soln. is eliminated by adding enough sodium silicate to combine with the calcium in the water and form a protective coating of aluminium silicate on the metal. Mixtures of sodium carbonate and silicate are sold under the trade names *carbosil*, *pearl dust*, and *aquamol* for cleaning aluminium vessels. A. Rohrig studied the protective action of sodium silicate on aluminium against attack by soln. of sodium hydroxide and carbonate.

H. St. C. Deville said that aluminium can be fused with **potassium nitrate** without the least change, even at a red heat. If the temp. be high enough to decompose the nitre, the metal forms potassium aluminate with the liberated potassium oxide, and the reaction is sometimes accompanied by deflagration. Aluminium is purified by fusion with nitre in an iron crucible, but if the fusion be conducted in a fireclay crucible, aluminium silicide is formed, and this is readily oxidized by the alkalies. S. Mierzinsky found that nitre at a red heat oxidizes powdered aluminium, and a blue flame is produced. Nitre is sometimes used as an ingredient in aluminium flashlight powders. According to G. Roth, a mixture of aluminium powder and **ammonium nitrate** can be used as an explosive; the reaction is symbolized $3NH_4NO_3+2Al=3N_2+6H_2O+Al_2O_3$. A number of explosives in which ammonium nitrate and aluminium are mixed with carbon, hydrocarbons, with or without oxidizing agents, has been described by C. E. Bichel, H. von Dahmen, etc.—*e.g. ammonal*. C. and A. Tissier observed no change when a mixture of **calcium phosphate** and aluminium foil is heated to whiteness. A. Rossel and L. Frank found that many phosphates—*e.g.* **ammonium sodium hydrophosphate, sodium metaphosphate,** bone meal, phosphorite, and **magnesium pyrophosphate**—can be heated with aluminium with the formation of aluminium phosphide, alumina, and an aluminate, and some phosphorus is volatilized. If silica be simultaneously present, the whole of the phosphorus is volatilized: $6NaPO_3+10Al+3SiO_2=3Na_2SiO_3+5Al_2O_3+6P$. According to A. Duboin, a mixture of 3 mols of normal calcium phosphate with 8 gram-atoms of aluminium burns with a brilliant flame in air or in an atm. of hydrogen, and when the product of the reaction is treated with water, some phosphine is set free.

According to H. St. C. Deville,[13] the action of aluminium on any salt can be readily deduced from the action of the metal on the corresponding acid of the salt.

Hence, it could be predicted that in general aluminium will precipitate no metal, not even silver, from acid soln. of the sulphates and nitrates, and this is in agreement with F. Wöhler's observations; but, as C. and A. Tissier have shown, metals may be precipitated from hydrochloric acid soln. Likewise, in alkaline soln., silver, lead, and the more electropositive elements will be precipitated. According to G. A. Maack, the precipitation of metals from soln. of their salts by aluminium is usually easiest in alkaline or ammoniacal soln., less easy in acid soln., and most difficult in neutral soln. Soln. of nitrates are decomposed with the greatest difficulty, and soln. of the chlorides are decomposed most easily; and the addition of an alkali chloride to the nitrate soln. facilitates the reduction. The metallic precipitation is generally accompanied by the evolution of hydrogen. C. Formenti and M. G. Levi investigated the reduction of salts of gold, platinum, palladium, cadmium, lead, tin, beryllium, cerium, niobium, thorium, zirconium, chromium, uranium, thallium, zinc, iron, manganese, mercury, antimony, arsenic, bismuth, silver, copper, cobalt, nickel, silicon, and boron by aluminium. In many cases, the aluminium does not completely replace the metal which is contained in the salt, and the reduced metal is often mixed with more or less aluminium, forming an alloy. In other cases, the metal which first separates subsequently forms a basic salt or is oxidized. The reduction of metallic chlorides takes place the more readily the greater the difference between the heat of formation of aluminium chloride and that of the metallic chloride, and this is also the case with other salts.

The above statements are illustrated by the action of aluminium on **cupric salts.** According to G. A. Maack, neither a cold nor a hot soln. of copper nitrate is reduced by aluminium except in the presence of free acid or an alkali. S. Mierzinsky said that a green basic salt is obtained from the nitrate. G. A. Maack found that a dil. aq. soln. of cupric sulphate is slowly reduced in the cold, and S. Mierzinsky obtained dendrites or octahedra after the mixture had stood two days. G. A. Maack observed that the precipitation is accelerated if sulphuric acid, ammonium or sodium chloride, or sugar be present, and if a drop of potassium hydroxide be added, a dark red precipitate begins to form immediately. An ammoniacal soln. of cupric sulphate is not precipitated by aluminium; copper is immediately precipitated from a soln. of cupric chloride, but some hours are required with a soln. of cupric acetate. A. Cossa, and N. Tarugi applied the reducing power of aluminium on cupric salts to the quantitative determination of copper. With **silver salts,** G. A. Maack observed that aluminium precipitates the metal from a soln. of silver sulphate; F. Wöhler and G. A. Maack, from ammoniacal silver oxide; and A. Cossa, from silver chloride. S. Mierzinsky found that with a feebly acid or neutral soln. of silver nitrate the metal is precipitated in dendrites after standing about 6 hrs. A. Cossa, G. A. Maack, N. Tarugi, and C. H. Hirzel made similar observations; according to J. B. Senderens, aluminium hydroxide and nitric oxide are formed; S. Mierzinsky found that aluminium precipitates silver as a crystalline powder from an ammoniacal soln. of silver chloride, or chromate. F. Wöhler noted that aluminium in contact with zinc reduces a silver nitrate soln. so long as the two metals are in contact. Aluminium rapidly reduces gold from soln. of **gold salts.** C. Moldenhauer found that with an aq. soln. of potassium cyanoaurate: $6KAuCy_2+6KOH+2Al=6Au+12KCy+Al_2O_3+3H_2O$. C. H. Crowe studied the action of normal soln. of chlorides, sulphates, and nitrates of the sodium, potassium, and magnesium on aluminium.

According to J. Margottet, all metal chlorides excepting those of potassium and sodium are reduced from their aq. soln., but this statement cannot include the chlorides of the other alkali metals, and those of the metals of the alkaline earths, or the **magnesium salts.** Soln. of aluminium salts give aluminium hydroxide when treated with magnesium. G. A. Maack found that soln. of **zinc salts**—chloride, nitrate, or sulphate—are scarcely changed by aluminium, but both he and A. Cossa precipitated zinc from an alkaline soln. of zinc salts—hydrogen is at the same time evolved. G. A. Maack found that cadmium is slowly and partially precipitated by aluminium from an ammoniacal soln. of **cadmium salts**; aq. soln. of cadmium chloride are completely reduced; soln. of cadmium sulphate are scarcely affected; and aluminium has no action on soln. of cadmium nitrate. According to S. Mierzinsky, **mercurous salts** are reduced by aluminium; for instance, an alcoholic soln. of mercurous chloride deposits mercury and this more quickly if the soln. be heated; and a soln. of mercurous and potassium iodides is similarly reduced. Aluminium decomposes soln. of the **mercuric salts**—chloride, cyanide, and nitrate: and also, according to G. A. Maack, the sulphate, potassium mercuric sulphide, nitrate at 50°-60°; or, according to A. Cossa, potassium mercuric iodide, and an alcoholic soln. of the chloride. In each case, the separated mercury forms aluminium amalgam, which then attacks the water, forming aluminium hydroxide and mercury. R. Varet found that with mercuric cyanide dissolved in water-free ammoniacal alcohol, a double salt of mercury and aluminium is formed. L. Bernegau studied the action of aluminium on the different salts of mercury. By treating a soln. of mercuric chloride with aluminium in the presence of water, or other solvent, Gehe and Co. found that a colloidal mixture of mercurous chloride, aluminium oxychloride, and hydroxide is produced.

II. St. C. Deville found that aluminium is attacked by soln. of **aluminium salts** with the evolution of hydrogen; and, according to C. Formenti and M. Levy, aluminium chloride is reduced to a subchloride. G. Lemoine found that the quantity of hydrogen set free is greater than corresponds with the amount of metal dissolved, and therefore inferred that aluminium acts catalytically on the decomposition of water. A soln. of **alum** does not attack the metal, but in the presence of sodium chloride the metal is dissolved with the evolution of hydrogen. In neither case has the salt any marked action, but the two salts jointly attack the metal severely. A. Cossa found that soln. of **thallium salts** are reduced by aluminium. According to G. A. Maack, **tin salts** are reduced by aluminium- soln. of stannous and stannic chlorides rapidly, and sodium stannate slowly—F. Wöhler obtained needle-like crystals of tin from a soln. of potassium stannate. Crystals of lead were found by S. Mierzinsky to be slowly precipitated by aluminium from soln. of **lead salts**—nitrate or acetate; G. A. Maack found a trace of lead was obtained from a soln. of lead nitrate after a week's time; and lead acetate is not affected even if the soln. be warmed. F. Wöhler said that no lead is precipitated from neutral or acid soln. of lead nitrate, but a lead-tree is obtained from alkaline soln.; some gas is developed at the same time. S. Mierzinsky found aluminium precipitates lead and chromic oxide from an alkaline soln. of lead chromate. A. Cossa also studied this reaction. G. A. Maack found that lead is obtained by leaving lead sulphate for some time in contact with aluminium and sulphuric acid. G. A. Maack found that **bismuth salts** are incompletely reduced by aluminium; soln. of **tungstates and molybdates** are reduced to blue lower oxides, and **uranyl sulphate** is likewise reduced. With manganese salts and aluminium, G. A. Maack found that the chloride is immediately decomposed while the sulphate and nitrate are scarcely, if at all, affected. W. Crookes found a boiling soln. of potassium permanganate slowly oxidizes aluminium. G. A. Maack found that **ferric salts**—chloride and sulphate—are slowly reduced, precipitating iron and giving off hydrogen; while **potassium ferrocyanide and ferricyanide** give blue precipitates. R. Böttger said that potassium ferricyanide is not reduced by aluminium. G. A. Maack found that **nickel and cobalt chlorides** are reduced by aluminium, and soln. of the other salts are but slowly changed. Soln. of **platinum salts** are rapidly reduced. A. Korczynsky studied the catalytic action of aluminium or its salts on the hydrogenation of aromatic hydrocarbons.

Some reactions of analytical interest.—The salts of aluminium have an acid, astringent taste, with a slightly sweet flavour, and, unless coloured by the acid radicle, they are colourless. The salts are not precipitated by hydrochloric acid, or hydrogen sulphide in acid soln.; aq. **ammonia** produces a white gelatinous or colloidal precipitate of aluminium hydroxide which is slightly soluble in the reagent, but is less soluble in the presence of ammonium salts. The precipitate is deflocculated or peptized when the salts are removed from the precipitate by washing; this is prevented by washing with a soln. of ammonium chloride or nitrate. Freshly precipitated aluminium hydroxide is readily soluble in dil. acids, but it is not so easily dissolved if it has stood for some time. F. Jackson[14] said that the precipitation of the hydroxide by ammonia can be detected in soln. containing one part of aluminium salt in 8000 parts of water. A similar precipitation occurs when **potassium or sodium hydroxide** is added to the soln. of aluminium salt, but in this case the precipitate is soluble in an excess of the reagent owing to the production of a soluble alkali aluminate, $Al(OM)_3$. The addition of a dil. acid to an alkali aluminate first precipitates aluminium hydroxide, and with a further addition all is dissolved. The aluminates are decomposed by the addition of ammonium salts. Aluminium hydroxide is soluble in tartaric, malic, citric, and many other organic acids, also in starch, sugar, etc. Hence, the presence of these compounds prevents the precipitation of aluminium hydroxide by alkali-lye, or aq. ammonia. Aluminium hydroxide is also precipitated by **ammonium sulphide** because the aluminium sulphide is hydrolyzed as fast as it is formed; by a boiling soln. of **sodium thiosulphate** owing to the hydrolysis of the aluminium thiosulphate; by acidifying the soln. with hydrochloric acid, and boiling with **sodium or ammonium nitrite,** as recommended by G. Wynkoop, and E. Schirm (iron, and chromium, but not zinc, manganese, cobalt, or nickel hydroxides, are precipitated); by adding **phenylhydrazine,** as recommended by W. H. Hess and E. D. Campbell, and E. T. Allen (chromium, titanium, zirconium, and thorium are precipitated, but not ferrous iron, beryllium, manganese, zinc, cobalt, or nickel); by **potassium, sodium, or ammonium carbonate or hydrocarbonate,** because the aluminium carbonate is hydrolyzed by water; and, according to J. N. von Fuchs, by **calcium or barium carbonate** suspended in water here, too, aluminium carbonate is presumably formed and hydrolyzed.

No precipitation occurs if an **alkali acetate** be added to a cold neutral soln. of an aluminium salt, but if the soln. be boiled the aluminium acetate is partially hydrolyzed, and a basic acetate, $Al(OH)_2(C_2H_3O_2)$, is precipitated. The reaction is reversible, for the precipitate redissolves as the soln. cools. The presence of tartaric acid and many other organic acids prevents the precipitation. Similar results are obtained with an **alkali succinate** or an **alkali formate.** Aluminium salt soln. give no precipitate with **alkali tartrates, alkali oxalates, tartaric acid, oxalic acid,** or **hydrofluosilicic acid**. A gelatinous precipitate of aluminium phosphate, $AlPO_4$, is produced when an **alkali or ammonium phosphate** is added to a soln. of an aluminium salt. The precipitate is soluble in mineral acids, but, unlike the phosphates of magnesium and of the alkaline earths, it is insoluble in acetic acid. Aluminium phosphate is soluble in alkali-lye, and when the soln. is boiled with ammonium chloride, a mixture of aluminium phosphate and hydroxide is precipitated; the addition of barium chloride to the soln. precipitates barium phosphate, and leaves the aluminate in soln.

If **potassium sulphate** be added to a conc. soln. of an aluminium salt, crystals of alum are formed. According to E. F. Anthon, **sodium tungstate** precipitates aluminium salts completely; and, according to I. von Ittner, **potassium ferrocyanide** gives a white precipitate slowly when cold, rapidly when heated the precipitate soon becomes green and blue. When tincture of **morin** is added to a dil. soln. of an aluminium salt, F. Goppelsröder obtained a fine green fluorescence not given by beryllium and the rare earths; a decoction of **campechy wood** was found by G. Horsley and E. Schumacher-Kopp, to give characteristic colours; and a **tincture of cochineal** was found by C. Luckow to behave similarly. According to F. W. Atack, **alizarin** gives a red colour which can be recognized when one part of aluminium is present in 10 million parts of soln. When aluminium compounds are heated with sodium carbonate on charcoal before the blowpipe, they give a white, infusible, brightly glowing oxide, which, when moistened with cobalt nitrate soln. and again heated, furnish a blue infusible mass of Thenard's blue.

Some uses of aluminium.—In its early days aluminium was unlucky in that exaggerated statements of its wonderful properties were in circulation. Anticipation transcended reality. The high place finally accorded to the metal fell short of first expectations. Some were disappointed, and exaggerated the importance of its defects. Hence, said H. Moissan[15]: *l'aluminium est le métal de l'avenir pour les uns, et le métal de la deception pour les autres.* J. W. Richards has said that one of the greatest metallurgical achievements of the nineteenth century was undoubtedly the addition of aluminium to the metals of everyday life. Aluminium is now manufactured in numerous forms, wires, bars, tubes, sheets, powder, foil, and ingots. It is used in the manufacture of domestic utensils. Its lightness, difficulty of corrosion, ease in keeping clean, and high thermal conductivity make its use for cooking-utensils particularly advantageous. It is used largely for military equipments when it is necessary to reduce to a minimum the weight to be carried by each soldier; it is used in the canteens, for buttons, belt-plates, tent-rings, the scabbards and handles of swords, etc. Its use in chemical laboratories for air-baths, water-baths, Bunsen burners, hot-water filtering funnels, and condenser tubes has been discussed by T. H. Norton; and its use in the construction of chemical plant by R. Seligman. It is used in the construction of surgical instruments—handles of knives and saws, speculum instruments, etc. Aluminium plates have been used as a substitute for the stone in lithographic work. Alloys with aluminium as the predominant metal are largely used for constructional purposes—parts of bicycles, motor cycles, motor cars, torpedo boats, yachts, aeroplanes, etc. The high electrical conductivity of aluminium and its non-magnetic properties enable aluminium or its alloys to replace much of the brass work in electrical apparatus. Its use as an electrical conductor was discussed by M. Wunder. It is used for portable telephone and telegraphic work—*vide supra*, electrical conductivity of aluminium. It is used for letters and signs to be attached to glass and wood. Aluminium-leaf is used as wrapping foil, and for decorative work, where it has largely superseded silver-leaf for this purpose. Powdered aluminium is used in large quantities as a decorative paint called by the trade-name *aluminium bronze*.

Aluminium is largely used in the manufacture of steel ingots and castings—A. Borsig, R. L. Packard, B. Talbot, etc. Up to 4 ozs. are added as the steel is being poured into the ingot moulds or group of moulds. It increases the soundness of the tops of ingots and thus decreases the scrap which more than compensates for the cost of the small proportion of aluminium used. Aluminium quietens the ebullition of steel. When steel, without the addition, is poured from the ladle into the ingot mould, it boils for 10–15 mins. before freezing at the top, and when freezing, it rises 8–10 ins. in the mould; with the addition of aluminium, the steel comes up to the required level and remains there, freezing over within 30–45 secs.; the steel is afterwards poured into the mould. The steel with the addition is more homogeneous; it has a greater tensile-strength; the castings have a smoother surface, and are less afflicted with blowholes. The aluminium removes any oxygen or oxides and acts as a deoxidizer. It also renders the steel less liable to oxidize during casting. Aluminium improves the casting of ordinary cast iron. The uses of aluminium in thermite reductions, and in the manufacture of explosives, and flash-light powders have already been described. J. W. Richards gives a list of about 200 commercial and technical applications of aluminium. Aluminium can be autogenously welded,[16] but the difficulty in soldering the metal is a disadvantage.

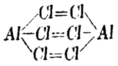
§ 6. The Atomic Weight and Valency of Aluminium

The hydrogen equivalent of aluminium approximates to 9. In 1812, J. J. Berzelius[1] gave AlO_3 for the formula of alumina; this made the at. wt. of the metal 9×6; but in 1826, after he had recognized the existence of sesquioxides, he wrote the formula Al_2O_3, and this made the at. wt. 9×3. T. Thomson, however, wrote the formula AlO, which made the at. wt. 18, and this view was adopted by J. L. Gay Lussac in 1833. L. Gmelin's equivalent number for aluminium, $9\times1\frac{1}{2}$, was based on the sesquioxide formula.

J. J. Berzelius' at. wt., 27 nearly, is in approximate agreement with Dulong and Petit's rule; it is in harmony with Mitscherlich's isomorphic rule applied to the oxides and salts of tervalent aluminium, iron, chromium, and manganese, and with the alums in which, besides the elements just mentioned, other tervalent elements—gallium, indium, thallium, titanium, vanadium, rhodium, ruthenium, and iridium—may take part. The location of aluminium in the third group of the periodic table as head of the family of certain elements of the rare earth series, emphasizes certain tervalent characters of this element. For a long time it was assumed that aluminium enters into combination as a sexivalent group Al_2 analogous to ferricum. The earlier determinations of the vapour density of aluminium chloride by H. St. C. Deville and L. Troost in the vicinity of 400° gave results corresponding with the formula Al_2Cl_6, but determinations at higher temp., 1000°, by L. F. Nilson and O. Pettersson[2] corresponded with the simpler formula $AlCl_3$; at intermediate temp., intermediate values are obtained since the reaction $Al_2Cl_6 \rightleftharpoons 2AlCl_3$ is involved. These results were confirmed by C. Friedel and J. M. Crafts, Fig. 59. In 1865, W. Odling and G. B. Buckton prepared aluminium methide, $Al(CH_3)_3$; and L. Roux and E. Louise showed that the vapour density of aluminium ethide, near the b.p., corresponds with $Al_2(C_2H_5)_6$, and at a higher temp. the compound decomposes. G. Quincke, however, found that "when the vapour density is determined at as low a temp. as possible—a few degrees above its b.p.—the results with aluminium methide agree with the formula $Al(CH_3)_3$, and not with $Al_2(CH_3)_6$ as reported by L. Roux and E. Louise, and V. Meyer." A. Combes also found that the vapour density of aluminium acetylacetonate, about 45° above its b.p., agrees with the formula $Al(C_5H_7O_2)_3$. A. Werner and W. Schmujloff found the mol. wt. of aluminium chloride in boiling pyridine to be $AlCl_3$, but the argument is faulty because pyridine forms a well-defined complex salt with aluminium chloride. E. P. Kohler found that the bromide and iodide in boiling carbon disulphide behave as if they had the doubled formulæ Al_2Br_6 and Al_2I_6; but in boiling nitrobenzene, aluminium chloride has the formula $AlCl_3$, and in freezing nitrobenzene, the bromide and iodide have the respective formulæ $AlBr_3$ and AlI_3. In general, if aluminium chloride unites with a solvent, it has the simpler mol. $AlCl_3$, but in an indifferent solvent like carbon disulphide, it has the doubled mol. formula—*vide infra*, aluminium chloride.

It was assumed that chlorine is univalent, and it therefore follows that in the doubled molecule, Al_2Cl_6, aluminium is at least quadrivalent $Cl_3\equiv Al-Al\equiv Cl_3$; and J. Traube tried to evade the difficulty by assuming that the aluminium is here sexivalent $Cl_3{\equiv}Al{\equiv}Al{\equiv}Cl_3$. E. P. Kohler, however, claimed that the explanation is simpler if it be assumed that one or more of the chlorine atoms are tervalent:



At higher temp., the molecule splits by breaking the double linkages of the chlorine atoms. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of a soln. of aluminium in tin, and inferred that the solute is in the mol. form Al_2; W. Ramsay likewise made a similar inference from the lowering of the vap. press. of mercury by aluminium. In both cases it is assumed that no compounds are formed.

J. J. Berzelius[3] made a single determination of the at. wt. of aluminium by igniting dry aluminium sulphate, and from the ratio $Al_2O_3 : 3SO_3$ so obtained, it follows that Al 27·31; H. Baubigny obtained 27·06 by an analogous process. W. W. Mather analyzed aluminium chloride, and from the ratio $AlCl_3 : 3AgCl$ computed Al 28·8. J. B. A. Dumas analyzed aluminium chloride, and from the ratio $AlCl_3 : 3Ag$ computed the at. wt. 27·45; H. Krepelka, 26·972 with Ag = 107·88, and Cl = 35·458; and J. W. Mallet from the ratio, $AlBr_3 : 3Ag$, 27·09. C. Tissier oxidized aluminium, and from the ratio 2Al : 30, computed 27·14; M. Isnard by a similar process obtained 27·0, J. Thomsen, 26·99, and E. Kohn-Abrest, 27·09. T. W. Richards and H. Krepelka analyzed aluminium bromide, and from the ratio $AlBr_3 : 3AgBr$ obtained for the at. wt. 26·963. A. Terreil heated aluminium in a stream of dry hydrogen chloride, and measured the hydrogen evolved, and from the ratio, Al : 3H, computed 27·4; J. W. Mallet treated aluminium with a soln. of sodium hydroxide, and by measuring the vol. of hydrogen computed 27·095 from the ratio Al : 3H, and he also burnt the hydrogen, and weighed the water; from the ratio $2Al : 3H_2O$ he obtained 27·07. J. Thomsen also determined the Al : 3H ratio by a process similar to that used by J. W. Mallet, and obtained 26·97; J. Torrey obtained 26·967; while E. Kohn-Abrest dissolved aluminium in hydrochloric acid, burnt the hydrogen to water, and so obtained 27·25 from the ratio $2Al : 3H_2O$. From these observations, B. Brauner deduces 27·05 ± 0·05, or 27·1, as the best representative value for the at. wt. of aluminium; and F. W. Clarke, 27·04. The International Table of Atomic Weights gives 27·1.

The **atomic number** of aluminium is 13. No **isotopes** have been detected by F. W. Aston.[4] E. Rutherford and J. Chadwick found that long-range particles were liberated from aluminium when bombarded by α-rays. These particles were assumed to be hydrogen nuclei produced by **the decomposition of the atoms of aluminium**. The distribution of momentum in terms of the initial velocity of the α-particles has been measured, and it is estimated that there is a 42 per cent. gain in energy as a result of the assumed disintegration of the aluminium. The **electronic structure** of the aluminium atom has been discussed by J. D. M. Smith, N. V. Sidgwick, etc.

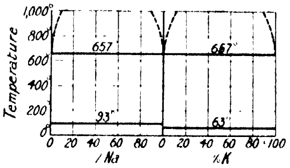
§ 7. Alloys and Intermetallic Compounds of Aluminium

Aluminium readily alloys with other metals and a large number of intermetallic compounds has been described. These compounds do not usually form solid soln. with one another or with the component metals, so that, as J. W. Richards,[1] and E. F. Law have emphasized, the useful alloys of aluminium with another metal M are those in which a small proportion of aluminium enhances the useful properties of the metal M; and those in which a small proportion of M imparts advantageous qualities to the aluminium. Bibliographies have been compiled by M. Sack, and P. D. Merica.

H. St. C. Deville[2] stated that aluminium readily unites with small proportions of *sodium*, and that one alloy with one to two per cent. of the alkali metal decomposes water in the cold. C. H. Mathewson found that molten sodium and aluminium are not mutually soluble, and form no compounds, Fig. 30; and D. P. Smith obtained similar results with *potassium* and aluminium, Fig. 31. The f.p. curves of the immiscible liquids have two arrests, one corresponding with the alkali metal and the other with aluminium. The dotted lines in the diagrams represent what is assumed to be the solubility curves of the one constituent in the other.



FIGS. 30 and 31.—Freezing-point Curves of Binary Mixtures of Aluminium with Sodium and Potassium.

J. Percy and A. Dick[3] seem to have been the first to draw attention to the alloys produced by adding aluminium to *copper*; they said that "a small proportion of aluminium increases the hardness of copper, does not injure its malleability, makes it susceptible of a beautiful polish, and varies its colour from red-gold to pale-yellow." C. and A. Tissier showed specimens in 1856, and the alloys were described a week afterwards by H. Debray. The last-named showed that aluminium unites with copper with the development of much heat—according to F. Tomlinson, the addition of 10 per cent. of aluminium to molten copper raises the temp. 134°; H. C. H. Carpenter said 40°. The term *aluminium bronze* is applied to alloys of copper and aluminium containing up to nearly 11 per cent. of the latter metal; thus, there are one per cent. bronzes, 5 per cent. bronzes, and the term without any qualification is understood to apply to 10 per cent. aluminium bronze.

The alloys can be produced by adding aluminium to molten copper, by thermite reactions; by thermoelectric reactions, etc.[4] Their manufacture has been discussed by R. J. Anderson. The constitution of the alloys has been the subject of many investigations.[5] H. C. H. Carpenter and C. A. Edwards' equilibrium diagram is shown in Fig. 32. There are seven solid phases designated α, α', β, γ, γ', δ, and ϵ; all are solid soln. There are two minima, one at 545° with 68 per cent. of aluminium, and one at 1038° with 9 per cent. of this metal. There is a maximum at 1050°

corresponding with the compound Cu_3Al, and another imperfect one at about 588° corresponding with $CuAl_2$. The solidus and liquidus curves of the α-phase lie rather *close together, so that the compositions of the portions which crystallize first are not very different from those which crystallize last.* There is a complex series of solid soln. containing less than 12·5 per cent. of aluminium. The character of these soln. depends on the rate of cooling, and different authorities are not in agreement as to the interpretation of the structure of alloys annealed at different temp. If the alloy with 10·7 per cent. of aluminium be used as the anode in a soln. of ferric chloride in dil. hydrochloric acid, the more electropositive constituent β dissolves, and the solid soln. α' remains in yellow grains approximating $4Cu+Al$ in composition. The system has also been studied by J. H. Andrew, B. E. Curry, S. H. Woods, M. Wählert, L. Guillet, A. A. Blue, B. Ohtani and T. Hemmi, D. Stockdale, T. Usihara, K. E. Bingham and J. L. Haughton, A. G. C. Gwyer, W. Campbell and J. A. Mathews, N. A. Puschin, H. Gautier, H. le Chatelier, C. T. Heycock and F. H. Neville, M. L. V. Gayler, P. D. Merica and co-workers, etc. J. D. Edwards studied the process of solidification of these alloys; and A. Portevin and G. Arnou, the effect of annealing on the structure and mechanical properties of the aluminium bronzes. O. Bauer and H. Arndt studied the segregation in these alloys. J. H. Chamberlain found that the changes in vol. which occur with alloys of aluminium with about 15 per cent. of copper are due to the absorption of the δ-alloy by the ϵ-alloy.

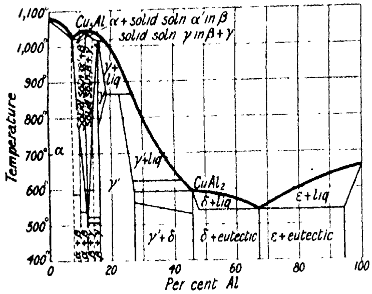


FIG. 32.—Equilibrium Diagram of Aluminium and Copper Alloys.

D. Stockdale showed that the temp., θ, of the liquidus curve of the copper-aluminium alloys with x per cent. of aluminium is $\theta=891+25x-x^2$, when x is between 9 and 18; and $\theta=169+97·4x-2·8x^2$, with x between 18 and 22. The maximum with the latter equation is 1016°, when $x=17·4$ per cent. D. Stockdale then argued that this maximum really represents a compound **copper hemialuminide,** Cu_2Al.

The **copper tritaluminide,** Cu_3Al, appears in the equilibrium diagram, and W. Louguinine and A. Schukareff made it by adding to fused copper about one per cent. more aluminium than corresponds with the formula. L. Guillet obtained it by a thermite reaction with cupric oxide and aluminium. The prismatic crystals are golden-yellow. K. Becker and F. Ebert, from the X-radiogram, found the side of the elementary cubic cells is 3·47 A. The sp. gr. at 20° is 7·52, so that there is a considerable contraction during the formation of the compound. H. Behrens gave 3·4 for the hardness. W. Louguinine and A. Schukareff gave 123·5 cals. per gram for the heat of formation. L. Guillet said that oxygen attacks it first at a high temp. and then very rapidly; moist carbon dioxide acts at ordinary temp.; chlorine at 200°, forming $AlCl_3$ and $CuCl_2$—the latter forms a protective skin on the alloy; boiling water or dil. potassium hydroxide does not perceptibly attack the compound; nitric acid dissolves it in the cold; sulphuric acid reacts giving hydrogen, sulphur dioxide, and sulphur; dil. hydrochloric acid has no action while the hot conc. acid attacks the alloy slowly; and it is dissolved by aqua regia. The equilibrium diagram does not show evidence of the existence of *copper aluminide,* CuAl, but L. Guillet claims to have made it as a grey powder by the thermite reaction with cupric oxide and aluminium, and treating the product with hydrochloric acid; and H. le Chatelier, by the action of dil. hydrochloric acid or potassium hydroxide on an alloy rich in aluminium. L. Guillet found its sp. gr. to be 5·76 at 20°—calculated by the mixture rule 5·02. W. Louguinine and A. Schukareff estimated its heat of formation to be 20·8 cals. per gram; L. Rolla gave 32·38 cals. per mol. L. Guillet found that the alloy is easily oxidized, but moist carbon dioxide has no action; it is attacked by a cold conc. soln. of potassium hydroxide; it is slowly attacked by sulphuric acid; dil. hydrochloric acid attacks it slowly, and the hot conc. acid more rapidly. The other reactions are like those for copper tritaluminide. The equilibrium diagram shows the existence of **copper dialuminide,** $CuAl_2$. L. Guillet made it by the action of cupric oxide on aluminium in the thermite reaction. G. Tammann and K. Dahl studied the brittleness and fracture of these alloys. W. Rosenhain reported that the X-radiogram of copper dialuminide corresponds with a face-centred lattice parallelopiped with edges 4·31 A. and 2·42 A. There the aluminium atoms approach within the range 2·42 A., whereas in the aluminium lattice the closest approach is 2·86 A. No application of external press. could force the aluminium atoms as closely together as they are in the compound. The quadratic prisms have a sp. gr. 5·37 at 20°—the value calculated from the mixture rule is 4·04. B. E. Curry gave 585° for the f.p. G. D. Roos gave 76·4 cals. per gram for the heat of fusion. W. Louguinine and A. Schukareff give 57·2 cals. per gram, and G. D. Roos gave 76·4 cals. per mol for the heat of formation. L. Guillet found the compound to be rapidly attacked by cold dil. potassium hydroxide; to be dissolved by boiling nitric acid; to be slowly attacked by sulphuric acid; and to be rapidly dissolved by cold hydrochloric acid. It is not dissolved by cold aqua regia, but is slowly attacked at a higher temp. A. Meyer found that a 10 min. immersion in a 4 per cent. alcoholic soln. of picric acid darkens $CuAl_2$ without affecting the remainder of the alloy.

W. Louguinine and A. Schukareff claim to have made a compound, *tetracopper enneaaluminide*, Cu_4Al_9, by melting the component metals. The sp. gr. of the silver-white crystalline mass is given as 4·118 at 20°, and the sp. ht. as 0·1502. They also reported *copper trialuminide* to be formed as a silver-white crystalline mass of sp. gr. 4·042 at 20°, and sp. ht. 0·1586 between 20° and 100°. G. D. Roos gave −13·53 cals. per mol for the heat of formation. There is no evidence that these products are anything more than solid soln.

According to H. C. H. Carpenter and C. A. Edwards, the **colour** of the alloys of copper and aluminium was silver-white when over 25 per cent. of aluminium was present; as the proportion of the latter metal is decreased the colour became pale-grey, lead-grey, and a reddish tinge appeared with 18 per cent. of aluminium; the colour passed through different tints of red and was a pale golden-yellow with 8 per cent. of aluminium; and with less than 3·5 per cent. of aluminium, the colour of copper appeared. C. and A. Tissier, H. Behrens, F. Regelsberger, W. Campbell, W. Louguinine and A. Schukareff, L. Guillet, A. M Portevin, E. H. and A. H. Cowles and C. F. Mabery, P. Morin and E. H. Moreau, etc., have made observations on the colour of these alloys. H. Behrens, and most of the observers on the constitution of the alloys have studied the **internal structure**; E. C. Bain, W. Rosenhain, A. Westgren and G. Phragmen, and K. Becker and F. Ebert, the **X-radiograms**; W. Fränkel and R. Seng, A. M. Portevin and J. Philippon, and A. A. Blue, the heat treatment; W. Campbell, the **fracture** of the alloys; and O. Bauer, the **liquation.** H. C. H. Carpenter and C. A. Edwards, W. Louguinine and A. Schukareff, L. Guillet, L. Schleiffarth, A. Riche, G. W. A. Kahlbaum and E. Sturm, B. Ohtani and T. Hemmi, etc., have measured the **specific gravity**; C. and A. Tissier, H. Debray, H. Behrens, H. C. H. Carpenter and C. A. Edwards, J. D. Edwards and T. A. Moormann, F. Auerbach, K. Bornemann and F. Sauerwald, B. W. Hales, and J. G. A. Rhodin investigated the method of estimating the composition of aluminium copper alloys from sp. gr. The dilatometric transformation was investigated by P. Braesco; the **specific volume,** by K. Bornemann and F. Sauerwald; the **hardness,** by T. Isihara, B. Ohtani and T. Hemmi, C. and A. Tissier, H. Behrens, L. Guillet, B. E. Curry, etc.; the **age-hardening,** by M. L. V. Gayler; the at. vol. of the solute atoms, by A. L. Norbury; G. Tammann and K. Dahl, the **brittleness**; the **malleability** and **ductility**, by B. E. Curry and S. H. Woods, L. Guillet, F. W. Webb, H. Tomlinson, W. Rosenhain, P. Morin and E. H. Moreau, P. Breuil, etc.; the **tensile strength**, by H. C. H. Carpenter and C. A. Edwards, J. O. Arnold, B. Ohtani and T. Hemmi, A. Portevin and F. le Chatelier, E. le Blant, A. Morley and G. A. Tomlinson, H. Lange, L. Schleiffarth, L. Tetmeyer, H. le Chatelier, A. K. Huntington, R. A. Hadfield, G. Tammann and K. Dahl, etc.; the **elastic modulus**, and the recovery of the alloy from overstrain, by A. Morley and G. A. Tomlinson; and the **sonorousness**, by the Chemische Fabrik Schering. H. le Chatelier, and P. Hidnert measured the **thermal expansion**; J. W. Richards, the **thermal conductivity**; W. Louguinine, the **specific heat**; and W. Louguinine and A. Schukareff, G. D. Roos, and L. Rolla, the **heat of formation**. P. Breuil, L. Sempell, and those who have studied the constitutions have made observations on the **melting point**. K. Bornemann and F. Sauerwald, and H. Alterthum studied the dissociation of copper aluminide at different temp. The **electrical conductivity** and **electrical resistance** have been studied by R. Benoit, L. Guillet and M. Ballay, L. Weiler, W. Broniewsky, H. le Chatelier, O. D. Chwolson, and G. W. A. Kahlbaum. The electrical conductivity of copper-aluminium alloys, measured by K. Bornemann and K. Wagemann, shows a maximum between 30–40 at. per cent. of aluminium, a marked change of direction corresponding with $CuAl_2$, a less distinct one with $AlCu_3$; and a maximum with 80–90 at. per cent. of aluminium. W. Broniewsky found the electrical conductivity curve corresponded with the existence of Al_2Cu_3. The **electromotive force** of the cell Al | $Ca(OH)_2$ soln. | Cu_nAl was measured by N. A. Puschin; and the electrolytic valve action and electrolytic corrosion by W. S. Rowland; and the **thermo-electric properties**, by H. Pécheux. The effect of tin on copper-aluminium alloys was studied by M. Wählert. The *Reports on the Light Alloys* (London, 1921) by the Advisory Committee for Aeronautics describes the properties of cupriferous aluminium alloys.

H. St. C. Deville said that aluminium bronze cannot differ much from the other alloys of copper, but B. S. Proctor found that it has a small advantage over ordinary brass in its power to resist corrosion, and its surface, when tarnished, is more easily cleaned. E. Wilson found that the attack by the atm. increases as the proportion of copper is raised. H Stockmeier, and R. Kayser found that aluminium bronze slowly decomposes water at 20°, and more rapidly at 60°. Observations on the corrosive action of sea-water, and soln. of various salts have been made by A. Ditte, H. C. H. Carpenter and C. A. Edwards, J. W. Richards, H. le Chatelier, W. S. Rowland, H. Behrens, etc. C. F. Mabery found hydrogen chloride gas removes all the aluminium from heated aluminium bronze. M. Balland, H. Moissan, and E. Defacqz examined the action of hydrochloric acid; W. Louguinine and A. Schukareff, of bromine water; H. Behrens, of sulphuric acid; J. W. Richards, of nitric acid; and F. Schultze, of some organic acids. C. and A. Tissier, and L. Petit-Devaucelle have made observations on this subject. B. S. Proctor found ammonia and coal gas have a slight action; H. St. C. Deville found hydrogen sulphide attacks the alloy less readily than the copper alloys.

H. St. C. Deville,[6] and C. R. A. Wright found that aluminium and *silver* are readily alloyed by direct fusion. All alloys with less than about 50 per cent. of silver are more fusible than aluminium, as illustrated by the fusion curves, Fig. 33. L. Guillet made the alloys by reducing silver oxide by the alumino-thermic reaction. C. Tissier fused aluminium with silver sulphide, and found aluminium sulphide in the slag. M. Rietz and M. Herold made aluminium-silver alloys by electrolysis. G. I. Petrenko constructed the fusion curve diagram shown in Fig. 33. The f.p. falls from the m.p. of aluminium to that of the eutectic at 567°; on the rising curve there is a break at 721° and 11·15 per cent. of aluminium corresponding with **silver hemialuminide**, Ag_2Al; and another break at 771° and 7·72 per cent. of aluminium corresponding with **silver tritaluminide**, Ag_3Al. Both compounds are dimorphous, and form solid soln. as indicated in the diagram. C. T. Heycock and F. H. Neville, and H. Gautier also made observations on the f.p. curve of silver-aluminium alloys. C. H. Hirzel reported as silver-white alloys $AlAg_4$ of sp. gr. 9·374; $AlAg_2$ of sp. gr. 8·744; and AlAg of sp. gr. 6·733. G. Guillet claimed to have made Ag_4Al_3 by the action of dil. hydrochloric acid on the powdered trita- or hemi-aluminides; he gave 7·08 for the sp. gr., and said that it is not soluble in nitric acid, or in cold hydrochloric acid; and dissolves slowly in hot sulphuric acid. H. Behrens, and G. I. Petrenko studied the microstructure of these alloys. C. T. Heycock and F. H. Neville made X-ray photographs of sections of the 4Al+Ag-alloy. In general, the addition of a little silver to aluminium makes the metal whiter, increases its hardness, enables it to take a better polish, and makes it denser and stronger. G. le Grix and W. Broniewsky measured the hardness of the alloys, and found a maximum corresponding with *silver ditritaluminide*, Ag_3Al_2, and a minimum with silver tritaluminide. G. Tammann and K. Dahl investigated the brittleness, and fracture. The so-called *tiers-argent* is an alloy made by C. and A. Tissier with two-thirds aluminium and one-third silver: it has many advantages over silver-copper alloys. The alloy with 5 per cent. of silver has a high malleability, and a sp. gr. 2·8. Both these alloys have been made into dessert-spoons, forks, and articles generally made of silver. The so-called *aluminium-silver* is an alloy of copper, nickel, and aluminium. G I. Petrenko said that alloys with up to 7·72 per cent. of aluminium are quite stable in air. H. Debray said that the alloy with 3 per cent. of silver is not attacked by hydrogen sulphide; on the contrary, S. Mierzinsky said that every alloy of silver and aluminium is more quickly attacked by this gas than silver alone, and in this statement, added J. W. Richards, the latter is wrong. G. le Grix and W. Broniewsky measured the electrical conductivity of the alloys at different temp. N. A. Puschin found that the e.m.f. of the cell Al | $Ca(OH)_2$ soln. | Ag_xAl showed a break corresponding with *silver aluminide*, AgAl, but not with Ag_2Al and Ag_3Al, but W. Broniewsky showed that such an alloy always has a heterogeneous structure. W. Broniewsky measured the thermo-electric force, and C. A. Kraus, the electrical conductivity.

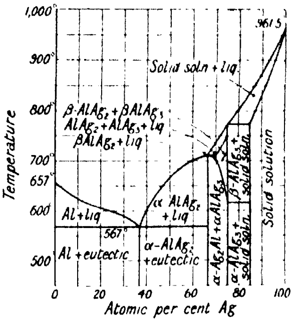

FIG. 33. Freezing-point Curve of Mixtures of Silver and Aluminium.

C. and A. Tissier[7] said that aluminium can carry as much as 10 per cent. of *gold* without impairing its malleability or ductility; but W. C. Roberts-Austen found that the addition of a small amount of aluminium quickly lowers the malleability of gold. C. T. Heycock and F. H. Neville found that the addition of aluminium to gold lowers the f.p. of the latter metal, and an alloy containing 21·5 at. per cent. of aluminium freezes as low as 525°, Fig. 34. Further addition of aluminium raises the f.p. until a maximum is reached at 625°, corresponding with **gold hemialuminide**, Au_2Al. The f.p. curve then falls again, reaching another minimum or eutectic point at about 570°, corresponding with 40 at. per cent. of aluminium. From that point, the curve rises rapidly to 1060°, the f.p. of **gold dialuminide**, $AuAl_2$, the purple compound discovered by W. C. Roberts-Austen. After passing this maximum, the curve falls again and has a minimum close to the f.p. of pure aluminium. This curve, on which a large number of points has been determined, shows the existence of the compounds Au_2Al and $AuAl_2$, whilst other singularities, less well marked than those mentioned, point to the formation at various stages of less stable compounds, probably **gold tetritaluminide**, Au_4Al; **gold trialuminide**, Au_8Al_3 (or Au_5Al_2); and **gold aluminide**, AuAl. As the curve is followed, the different substances that crystallize out may be traced in the changing colour of the alloys, which are at first yellow, owing to the presence of free gold, then white, *then purple, and finally white again as the aluminium end of the curve is reached. C. T. Heycock and F. H. Neville further studied alloys with up to 5 per cent. of aluminium. The inset in Fig. 34 is an enlargement of the diagram about the first eutectic, indicated the existence of two series of solid soln. (α and β), and of the* compound Al_3Au_8. This compound is found in all the alloys containing from 18 to 28 atomic per cent. of aluminium. Recalescence phenomena associated with the cooling curves of alloys containing from 10 to 27 atoms per cent. of aluminium point also to the formation of $AlAu_4$. J. A. Matthews could not prepare gold dialuminide.

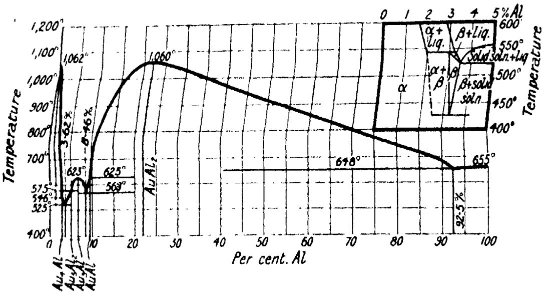

FIG. 34.—Freezing-point Curve of Mixtures of Aluminium and Gold.

G. F. Andrews found the colour of gold-aluminium alloys:

	White	Pale violet-brown	Very pale violet	Violet	Pinkish-violet	Pale violet	Violet-pink
Per cent. gold	5	10	15	50	78	90	94

The alloys are said to be of little practical use except for decorative purposes. The so-called *Nürnberg gold* is a ternary alloy approximating copper, 90; gold, 2·5: and aluminium, 7·5 per cent. C. T. Heycock and F. H. Neville, and W. C. Roberts-Austen and F. Osmond studied the minute structure of these alloys; C. T. Heycock and F. H. Neville, X-radiograms; W. C. Roberts-Austen, the m.p., the tensile strength, and the elongation of the gold-aluminium alloys; and C. H. Desch, the eutectic mixtures. W. C. Roberts-Austen showed the great heat of combination by melting 30 grms. of gold in a crucible and keeping the temp. at 1155°; 0·3 grm. of cold aluminium was stirred into the molten metal. The temp. fell to 1045°, and then rose briskly to 1380°—*i.e.* 225° above the initial temp. of the gold.

F. Wöhler[8] prepared an alloy of aluminium and with 8·6 per cent. of *calcium* by melting approximately equal parts of sodium and aluminium with a large excess of calcium chloride. He regarded the alloy as a mechanical mixture, but found it to be acted upon by neither air nor water. Poulenc Frères and M. Meslans, and E. Jüngst and R. Mewes also prepared calcium-aluminium alloys. K. Arndt noted the great development of heat when the two metals are combined under molten potassium chloride. L. Donsky found that the f.p. curve, Fig. 35, shows two eutectic points at 610° and 6·1 per cent. (components aluminium and $CaAl_3$) and 550° and 75 per cent. (components calcium and $CaAl_3$) of calcium respectively. Between 16 per cent. and 43 per cent. of calcium, the alloys separate into two liquid layers, which react at

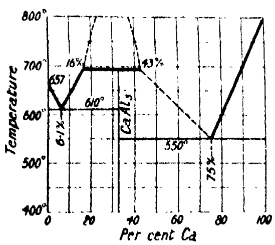

FIG. 35.—Freezing-point Curves of Mixtures of Aluminium and Calcium.

692° to form **calcium trialuminide**, $CaAl_3$. Alloys containing 0–8 per cent. of calcium have the colour of aluminium, and are somewhat harder than that metal. Those containing a moderate amount of calcium are brittle and porous, and those rich in the latter metal are less brittle and are unstable in the air. J. M. Breckenridge studied the electrical conductivity of these alloys and found a break in the curve with $CaAl_3$; the electrochemical potential curves of these alloys also gave a maximum corresponding with $CaAl_3$. O. Ruff and H. Hartman studied the action of nitrogen on a heated alloy of calcium and aluminium. Alloys of *barium* and aluminium were made by E. Jüngst and R. Mewes. E. Stansfield made an alloy with 60 per cent. of barium by the thermite process. N. N. Beketoff also claimed to have made an alloy with 24–33 per cent. of barium by melting a mixture of barium chloride and hydroxide with aluminium. If barium chloride alone be used, the aluminium floats on the molten chloride without reaction. E. Beckmann obtained results different from those of N. N. Beketoff—*vide supra.* C. Vickers tried the effect of barium on aluminium, but with no favourable results.

G. Oesterheld[9] found that molten *beryllium* and aluminium are miscible in all proportions, but they do not form a *beryllium aluminide*. The f.p. curve, Fig. 36, has two branches with a eutectic at 644° and 4 at. per cent. of beryllium. Solid soln., *α*, are obtained at the beryllium end of the series with up to 3 at. per cent. of aluminium. J. Parkinson[10] prepared an alloy of aluminium and *magnesium* by melting the two metals under a layer of sodium chloride (not fluorspar or cryolite) in a crucible lined with magnesia. L. Mach used a similar process with potassium chloride as a flux. F. Wöhler made an alloy of aluminium with 30·8 per cent. of magnesium, and found it to be tin-white and brittle, and to ignite at a red heat, burning with a flame like that of magnesium alone; he also made an alloy with 64 per cent. of magnesium which was malleable, and was destroyed without evolving hydrogen after leaving it in contact with water for a day. Both alloys appear to contain a definite compound because when treated with a soln. of ammonium chloride, they disengage hydrogen abundantly, and deposit a brilliant, tin-white, metallic powder—insoluble in a soln. of ammonium chloride or of sodium hydroxide. It burns with brilliant sparks when thrown into a flame. H. Pécheux made alloys by melting the components out of contact with air; E. Jüngst and R. Mewes, by heating magnesium chloride with sufficient aluminium to volatilize all the chlorine as aluminium chloride; and the Deutsche Magnaliumgesellschaft, by the electrolysis of molten magnesium halides—*e.g.* tachhydrite or carnallite—with an alloy of magnesium and aluminium as cathode.

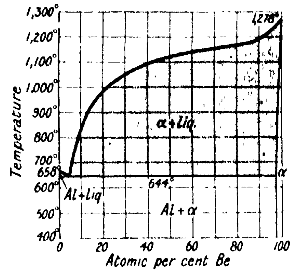

Fig. 36.—Freezing-point Curve of Mixtures of Beryllium and Aluminium.

The m.p. have been studied by O. Boudouard, who found maxima corresponding with $MgAl_4$, MgAl, and Mg_2Al, but these conclusions are not reliable since too few a number of mixtures were examined, and only the initial f.p. were determined. More detailed observations were made by G. Grube, and G. Eger, who found evidence of the formation of Al_3Mg_4. H. Schirmeister made some observations on the f.p. of these alloys. G. D. Roos gave 164·8 Cals. for the heat of formation of Mg_4Al_3, and W. Biltz and G. Hohorst, 49 cals. The last-named also gave 2·151 for the sp. gr. of Mg_4Al_3 at 25°/4°, and 83·0 for the mol. vol. K. Becker and F. Ebert found from the X-radiogram that the length of side of the cubical cells was 4·80 A., and sp. gr. 2·62. The results of D. Hanson and M. L. V. Gayler are illustrated by Fig. 37. They found maxima corresponding with **magnesium ditritaluminide**, Mg_3Al_2, and with **magnesium sesquialuminide**, or *trihemialuminide*, Mg_2Al_3. It will be observed that the compound Mg_3Al_2 does not occur just at the maximum, and this may be due to the decomposition of the compound when it is melted, for the presence of a compound is shown on the liquidus curve either by a maximum, or by a point of inflection; the former occurs when the dissociation temp. of the compound lies above the f.p. curve, and the latter when it lies below one of the branches of the curve but not below the eutectic. The maximum on the diagram corresponds with G. Grube's **magnesium tri-tetritaluminide,** Mg_4Al_3. This compound also appears on the ternary diagram of magnesium, aluminium, and copper, Fig. 38. The fact that D. Hanson and M. L. V. Gayler found the alloy 4Mg+3Al to melt over a range of temp. of 5° led them to infer that the existence of Mg_4Al_3 has not been definitely established. B. Ohtani. and P. D. Merica and co-workers studied the thermal diagram of these alloys.

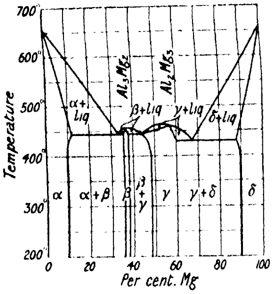

FIG. 37.—Freezing-point Curve of Mixtures of Magnesium and Aluminium.

According to G. Grube, the microscopic structure of the magnesium-aluminium alloys showed that those containing 0–35 per cent. of aluminium consist of primary crystals of solid soln. rich in aluminium, surrounded by another solid soln. with about 35 per cent. of magnesium. With about 30 per cent. of magnesium the primary crystals are dendritic, and this led O. Boudouard to assume the existence of a compound Al_4Mg. Alloys with 35–54 per cent. of magnesium consist of a homogeneous solid soln.; those with 54–68 per cent. of magnesium consist of crystals assumed to be Al_3Mg_4 embedded in a eutectic; and alloys with 68 to 100 per cent. of magnesium consist of crystals of magnesium embedded in a eutectic. D. Hanson and M. L. V. Gayler, and B. Ohtani also studied the micro-structure of these alloys; and K. Becker and F. Ebert the X-radiograms. The alloys with 10–15 per cent. of magnesium are silver-white, polish readily, have a fine grained fracture, a sp. gr. which increases as the proportion of magnesium rises, the m.p. is between 600° and 700°; and the sp. ht. exceeds that of aluminium. According to A. Wilm, alloys containing small quantities of magnesium are hardened by quenching, but the process is quite different from the hardening of steel. If quenched from 500° in cold water, the metal is at first soft, but the hardness increases in the course of a few days. The initial hardness is independent of the quenching temp., but the hardness attained after storage increases with the quenching temp. up to 470°, beyond which it is constant. Quenched duralumin was shown by E. Heyn and E. Wetzel to undergo an appreciable expansion on standing. K. Becker and F. Ebert examined X-radiograms of these alloys; J. T. Rooney, B. Ohtani, M. Hanzel, L. Aitcheson, etc., studied the mechanical properties of these alloys. Alloys of magnesium and aluminium containing 5 to 30 per cent. magnesium have approximately the same mechanical properties as brass and are used for making screws, nuts, wire, tubes, and sheets. The hardness increases with the magnesium content. With 70 per cent. magnesium, the alloy is as hard as mild steel. The tensile strength of alloys containing 2 to 10 per cent. magnesium is considerably improved by quenching from about 500°. M. L. V. Gayler studied the age hardening of these alloys. J. Schumann and L. Mach studied the reflection of light of wave-length 1850–2800 on these alloys. C. A. Kraus, and B. Ohtani studied the electrical conductivity of these alloys. J. Klaudy and A. Miethe have studied the chemical reactions of the alloys, and found that their behaviour closely resembles that of aluminium. H. Pécheux said that alloys with 15–34 per cent. of magnesium are not changed in air; they are readily attacked by conc. and dil. acids, but sulphuric acid does not attack the alloys rich in aluminium. L. Rolla studied the corrosion of these alloys. Distilled water and hydrogen peroxide readily attack all the alloys especially if the alloys be in the form of filings, $Mg+2H_2O=Mg(OH)_2+H_2$. Potassium hydroxide soln. acts more quickly the higher the proportion of contained aluminium. An aq. soln. of cupric sulphate acts vigorously, $3CuSO_4+2Al=Al_2(SO_4)_3+3Cu$.

Ternary alloys of magnesium, aluminium, and copper, have been studied by R. Vogel, and M. L. V. Gayler. R. Vogel's observations are summarized in Fig. 38. The stippled regions show the zones of existence of various forms of mixed crystals with the ternary compound **copper tetramagnesium hexaluminide,** $CuMg_4Al_6$. L. Mach patented alloys with from 2–30 parts magnesium to 100 parts of aluminium —possibly alloyed with a little copper, nickel, etc., in such proportions that the sp. gr. of the alloy does not exceed that of aluminium. The alloys are called by the trade name *magnalium*. The Deutsche Magnaliumgesellschaft raised the m.p. by adding antimony. Magnalium has also been discussed by R. E. Barnett, W. G. H. Wolff, J. Klaudy, etc. Magnalium has two advantages over aluminium; its tensile strength is greater, and it can be filed, drilled, and turned much cleaner without dragging, tearing, or clogging the tool. It is more liable to oxidize when hot. R. E. Barnett said it is less liable to corrosion in the atm. of a laboratory than is zinc, copper, or brass. The alloys on the market show Cu, 1·76; Mg, 1·60; Ni, 1·16 with traces of iron and antimony; Sn, 3·15; Cu, 0·21; Mg, 1·58; Pb, 0·72; and about 0·3 per cent. of iron. Another sample was intermediate in composition. J. Disch measured the thermal expansion of *electron*—an alloy of aluminium and magnesium—between −190° and about 300°. H. S. Rawdon and co-workers studied the attack by corrosive liquids. The alloy *duralumin*, introduced by A. Wilm, contains over 90 per cent. of aluminium; about 0·5 per cent. of magnesium; 3·5–5·5 per cent. of copper; and 0·5–0·8 per cent. of manganese. Duralumin has been studied by C. Grard, K. R. Koch and C. Dannecker, C. Fendler and W. Stueber, L. Guillet and co-workers, A. Giannelli, E. Heyn and E. Wetzel, L. M. Cohn, and J. McKechnie. The sp. gr. ranges from 2·75 to 2·84; the m.p. is near 650°; the Brinell's hardness is 60–70. By cold-working annealed duralumin, high degrees of strength can be obtained. Unlike most high-aluminium alloys, duralumin can be hardened by quenching like steel, but unlike steel, it does not matter whether the hardening process is applied to the annealed or cold-worked material. Duralumin exhibits the remarkable property of ageing. When annealed and quenched, it shows no signs of increased hardness, but there is a perceptible increase after it has stood an hour, and the hardness increases more rapidly up to the sixth hour, and the increase continues for about 48 hrs., after which no further change is perceptible. S. Konno, and E. Heyn and E. Wetzel studied the changes in length during the ageing of duralumin; K. L. Meissner, the corrosion; and A. Knerr, the welding and soldering of duralumin. B. Ohtani, and V. Fuss also studied the ternary system Mg—Al—Cu.

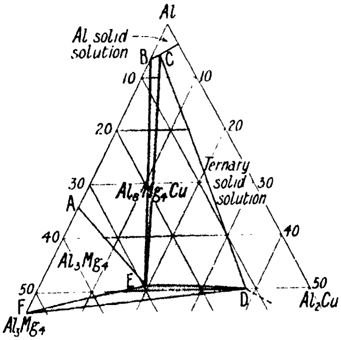

FIG. 38. Ternary System, Al—Al_3Mg_4—Al_2Cu.

The first aluminium made by H. St. C. Deville [11] contained *zinc* derived from the retorts which had been made from a mixture of fireclay and old zinc retorts crushed to small fragments (grog). H. Debray found aluminium with 3 per cent. of zinc was harder than aluminium and quite malleable; C. and A. Tissier also made alloys of these two metals, which, said A. H. Sexton, readily unite when in the molten state. C. R. A. Wright reported that the two metals form "true" alloys and that

they are miscible in all proportions. Some of the early solders for aluminium were made of zinc with from 6–20 per cent. of aluminium. R. Basset, M. Dullo, and A. W. S. van Oldruitenborgh, made zinc-aluminium alloys by reducing sodium aluminium chloride with zinc; C. H. Hirzel, by melting the two metals under a layer of sodium or potassium chloride; E. D. Self, by adding zinc to aluminium melted in a graphite crucible, and preventing oxidation by fat; and E. S. Shepherd, by using graphite crucibles free from silicates and preventing oxidation by coal gas

The constitution of the alloys has been studied by H. Gautier, T. Hemmi, G. Charpy, C. T. Heycock and F. H. Neville, W. Sander and K. L. Meissner, A. S. Federoff, E. S. Shepherd, G. Eger, A. Ssaposhnikoff, A. Sturm, O. Bauer and O. Vogel, M. Wählert, H. Pécheux, E. Crepaz, L. Losana and E. Carozzi, J. L. Haughton and K. E. Bingham, etc. The equilibrium diagram shown in Fig. 39 is due to W. Rosenhain and S. L. Archbutt. The eutectic line to the right of the point *F*, Fig. 39, is metastable, and it disappears if the reaction along the line *E* is completed by sufficiently slow cooling, or by annealing at 400°. They established the formation, at 443°, of dendritic crystals of unstable **zinc ditritaluminide**, Zn_3Al_2 which decompose at 256° with a vigorous evolution of heat. The solid soln. are α, β, γ, and δ. The existence of the unstable aluminide was not shown by E. S. Shepherd's equilibrium diagram, and he assumed that the alloys are formed of two solid soln. The curves for the thermoelectric power, and the rate of change of thermoelectric power with temp., Fig. 42, as well as the electrical conductivity, and the temp. coeff. of the resistance, Fig. 41, by W. Broniewsky, are typical of alloys which are soluble in one another to a limited extent, and in which the solid soln. thus formed mix with each other mechanically. The central portions of the curves are nearly linear and are typical of mechanical mixtures.

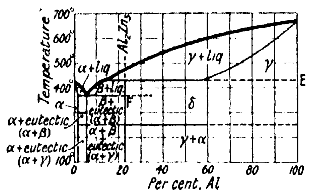

FIG. 39.—Equilibrium Diagram of Mixtures of Zinc and Aluminium.

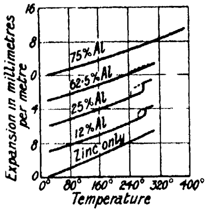

FIG. 40.—Thermal Expansion of Zn-Al Alloys.

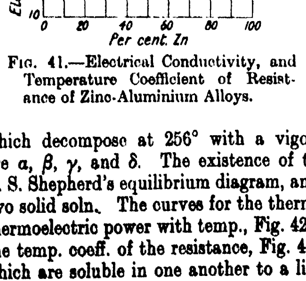

FIG. 41.—Electrical Conductivity, and Temperature Coefficient of Resistance of Zinc-Aluminium Alloys.

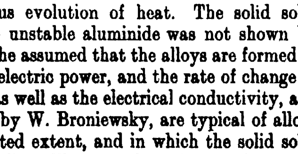

FIG. 42.—Thermoelectric Power, *E*, at 0° of Zinc-Aluminium Alloys.

The microstructure of the alloys has been examined by E. S. Shepherd,

W. Campbell, E. A. Lewis, J. W. Richards, C. T. Heycock and F. H. Neville, W. Rosenhain and S. L. Archbutt. C. T. Heycock and F. H. Neville showed that there is no foundation for C. R. A. Wright's statement that the molten alloy separates into two layers. A. M. Portevin studied the microstructure of the eutectic. E. Heyn and E. Wetzel studied the vol. changes during the ageing of these alloys. E. S. Shepherd measured the sp. gr. and sp. vol.; K. Bornemann and F. Sauerwald, the sp. vol. and expansion, J. W. Richards, E. D. Self, W. Rosenhain and S. L. Archbutt, A. H. Sexton, T. Isihara, and A. Ssaposhnikoff, the hardness; A. Ssaposhnikoff, W. F. Durand, W. Rosenhain and S. L. Archbutt, the elastic modulus; the tensile strength, by C. R. Carpenter, G. Charpy, E. S. Sperry, E. Wilson, M. Bassé and M. Selve, and W. Rosenhain and S. L. Archbutt; and torsion tests, compression tests, alternating-stress tests, and impact tests, by W. Rosenhain and S. L. Archbutt. O. Bauer studied the liquation of these alloys and O. Bauer and H. Arndt, segregation in these alloys. W. Louguinine and A. Schukareff measured the heat of formation; E. Wilson, A. Schulze, and W. Smirnoff, the coeff. of thermal expansion. The results by A. Schulze are shown in Fig. 40. The disturbances in the curve are due to the formation of Al_2Zn_3. The dotted lines represent results on a falling temp., the others are on a rising temp. The m.p. were determined by J. W. Richards, W. F. Durand, and those who have worked on the equilibrium diagram, Fig. 39; and C. T. Heycock and F. H. Neville, the at. depression of the f.p. P. Braesco measured the heating curves. E. S. Shepherd said the surface tension is lower than that of aluminium, because the fluidity of the alloys is greater than that of aluminium. L. Schleiffarth found the addition of zinc to aluminium facilitates the production of sound castings. E. Wilson, A. Sturm, J. G. A. Rhodin, and B. W. Hales examined the method of estimating the composition of alloys of zinc and aluminium from the sp. gr. They found that copper and zinc have nearly the same influence on the sp. gr. of aluminium. A. Battelli, and H. Pécheux measured the electrical conductivity and resistance. W. Fränkel and E. Scheuer studied the effect of ageing on the electrical and mechanical properties. W. Broniewsky's curves for the electrical conductivity at 0°, and the temp. coeff. of the resistance between 0° and 100° are shown in Fig. 41; observations were also made by L. Holborn and E. Lechner. Measurements of the thermoelectric power against copper were made by H. Pécheux, and against copper by A. Battelli; W. Broniewsky's curves for the thermoelectric power, E, and of the rate of change of thermoelectric power per degree are given in Fig. 42. E. S. Shepherd found that these alloys are more stable than the other alloys of aluminium because of the close proximity of the component elements in the voltaic series. C. Montemartini and E. Colonna found that with dil. nitric acid between 7°–10°, with 1 grm. of alloy, the following amounts of ammonia are formed:

HNO_3 c.c.	2500	1000	120	70	45
HNO_3 Per cent.	0·25	1·00	10·00	27·5	45·0
Ammonia formed	0·00253	0·00758	0·02737	0·00641	0·00132 grm.

and with more conc. nitric acid, no ammonia is formed. L. Rolla studied the corrosion of these alloys. W. Rosenhain and S. L. Archbutt studied the corrosive action of sea-water. M. Wählert studied the effect of additions of iron. H. E. Brauer and W. M. Peirce measured the effect of impurities on the oxidation and swelling of these alloys.

Some zinc-aluminium alloys have received special trade-names, *e.g.*, the alloy with one-third zinc and two-thirds aluminium is called *alzene*.[12] There are two light aluminium alloys, *ziskon*, with about one-fourth its weight of zinc, and *zisium*, which was originally called *zalium*. Both have been prepared for use in making scientific instruments. C. d'Albert speaks of the use of alloys with 12–20 per cent. of zinc in the automobile industry. The Deutsche Gold- und Silber-Scheideanstalt patented the use of up to 0·5 per cent. of aluminium along with zinc, in Parkes' process for desilvering lead.

The ternary alloys of zinc, copper, and aluminium are called *aluminium brasses.* They are usually made either by adding aluminium to molten brass, or zinc to molten aluminium bronze. Combinations were studied by J. Bauer,[13] M. Wählert and M. G. Farmer. J. W. Richards said that Al-brasses flow well, give sharp sound castings, are more ductile and malleable, a greater tensile strength, and a greater power of resisting corrosion than ordinary brass. E. H. Schulz and M. Wählert, V. Fuss, and V. Jares studied the ternary system: Al—Cu—Zn; V. Fuss, Zn—Al—Mg; and M. Levi-Malvano and M. Marantonio, Cu—Zn—Cu_3Al. O. Bauer, and L. Rolla studied the corrosion of these alloys; and J. L. Haughton and K. E. Bingham, the constitution. H. C. H. Carpenter and C. A. Edwards have worked out the equilibrium diagram, Fig. 43. The areas *ABC*, *BCDE*, and *DEF* correspond respectively with the separation from the liquid of the α, β, and the constituents corresponding with γ, δ, ϵ, and the aluminide $CuAl_2$ of the copper-aluminium alloys. The boundaries of the phases in the last-named area have not been determined. There is no evidence on the liquidus surface of a true ternary compound or eutectic deposited from liquid alloys with over 40 per cent. of copper, though the curvature of the isothermal lines probably indicates the existence of a ternary eutectic near that point. The univariant line *BC* connects two non-variant points of the copper-zinc and copper-aluminium systems. J. L. Haughton measured the electrical conductivity of the Cu—Al—Zn alloys at different temp.

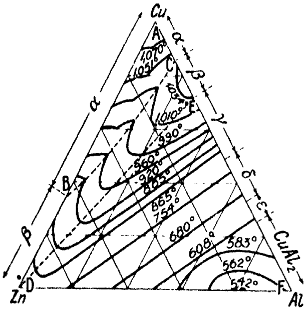

FIG. 43.—Isothermal Lines in the Equilibrium Liquidus Diagram of the Ternary System, Cu—Zn—Al.

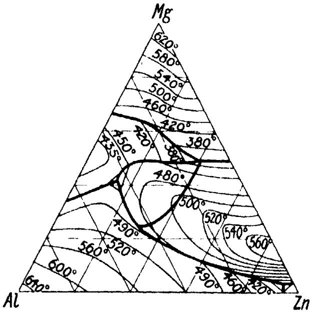

FIG. 44.—Isothermal Lines in the Equilibrium Diagram of the Ternary System, Zn—Mg—Al.

G. Eger constructed the equilibrium diagram, Fig. 44, of the ternary system Al—Mg—Zn. They are completely miscible in the liquid state, but in the solid state they are only partially soluble in one another. A peritectic horizontal in the Al_3Mg_4—Zn_2Mg system indicates the probable existence of the ternary compound **magnesium zinc aluminide,** $Mg_7Zn_6Al_3$, which decomposes on melting, and which is capable of forming solid soln. This system was also studied by W. Sander and K. L. Meissner. The *Reports of the Light Alloys* (London, 1921) by the Advisory Committee for Aeronautics describes the properties of many zinciferous aluminium alloys.

Cadmium readily forms alloys with aluminium. C. R. A. Wright[14] found that with equal parts of the two metals at 100° above the m.p., two layers are formed—the upper with 3·39 per cent. of cadmium, and the lower with 0·22 per cent. of aluminium. The presence of tin prevents the separation. W. Campbell and J. A. Mathews made observations on this subject, and A. G. C. Gwyer constructed the equilibrium diagram, Fig. 45. Here no compounds of the two elements are indicated.

H. St. C. Deville[15] said that *mercury* is not able to unite with aluminium, but something is wrong, for A. Cossa made aluminium amalgam by melting the two metals in an indifferent gas; and C. Tissier, by rubbing mercury on aluminium dipping in a soln. of potassium hydroxide. According to I. Fogh, also, H. C. Oersted made the amalgam in 1825. If the surface of aluminium be well-cleaned or moistened with the alkaline soln. a shining amalgam is formed immediately it comes in contact with the mercury. J. B. Baille and C. Fèry said that if aluminium foil be placed in a tube with mercury, it oxidizes rapidly, and becomes heated, while the mercury becomes covered with a thin layer of aluminium. By heating the two elements in an atm. of carbon dioxide in sealed tubes on a sand-bath, the amalgamation proceeds faster, the higher the temp., and the process is very active at the b.p. of mercury; the vapour of mercury does not attack aluminium, only liquid mercury attacks aluminium —*au contraire*, V. Biernacky, and N. Tarugi said that the vapour of mercury amalgamates with aluminium. L. B. Baille and C. Fèry continued that aluminium has a definite solubility in mercury. As the tubes containing the hot sat. soln. of aluminium in mercury are cooled, a crystalline paste separates, floating on the liquid. This paste was strained off, and heated in a current of hydrogen in a covered crucible so as to distil off the mercury. Arborescent crystals of aluminium remained; their composition corresponded with *mercury ditritaluminide*, Hg_3Al_2. A. Smits and G. J. de Gruijter measured the f.p. of mixtures of mercury and aluminium, and their results are indicated in Fig. 46. The curve is comparatively simple. No compound is formed. There is a slight break at about 580° corresponding with the transition-point of aluminium. W. Ramsay, V. Biernacky, C. John, and N. Tarugi made the amalgam by the direct union of the elements. P. Casamajor found that if aluminium, in contact with a zinc rod, be dipped into mercury covered with acidulated water, aluminium amalgam is formed.

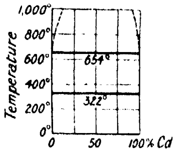

Fig. 45. Freezing-point Curves of Cadmium-Aluminium Alloys.

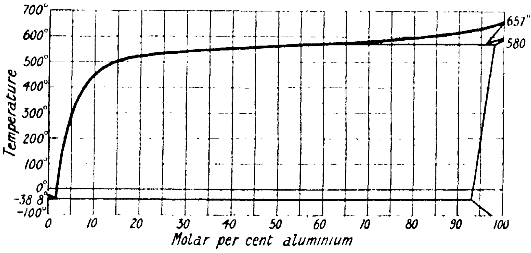

Fig. 46.—Freezing-point Curve of Mixtures of Mercury and Aluminium.

L. P. Cailletet, and C. Tissier made aluminium amalgam by the action of ammonium or sodium amalgam on aluminium in the presence of water. C. Klauer states that if potassium amalgam be introduced into a hole bored in a crystal of alum, it immediately acquires a rotary motion which sometimes continues for half an hour; at the same time, the alkali amalgam becomes more viscid, and takes up much aluminium. L. Bernegau found that dry aluminium gradually forms an amalgam if tubbed with mercury salts—C. Reichard used mercurous or mercuric oxide, or mercuric amidochloride alone or made into a paste with mercurous chloride —mercuric sulphide alone or mixed with mercurous chloride gives no amalgam, but, according to H. Hurt, if the sulphide be moistened with a soln. of sodium hydroxide or hydrochloric acid, an amalgam is formed. J. Schumann found a mixture of aluminium foil with 75 per cent. of mercuric oxide reacts vigorously when moistened with water. Aluminium with a clean surface obtained by washing with, say, a soln. of alkali hydroxide, is amalgamated when dipped in an aq. soln. of mercuric chloride. This process has been used by J. B. Cohen and co-workers, H. Wislicenus and co-workers, and E. Kohn-Abrest and co-workers. E. Kohn-Abrest said that aluminium foil is scarcely affected if the soln. of mercuric chloride be less conc. than 0·01 per cent., but the action increases as the conc. of the soln. increases. P. Nicolardot said that purified aluminium (99·2 per cent.) is more sensitive than this, for if the surface be clean, the action can be detected in soln. with a conc. less than 0·001 per cent. Both workers showed that the reaction is inhibited if the aluminium contains copper; but is not influenced by the traces of iron or silicon found in the commercial metal. J. P. Joule obtained aluminium amalgam by the electrolysis of soln. of an aluminium salt with a mercury cathode. L. P. Cailletet, C. Tissier, W. Kettembeil, and R. E. Myers used a similar process; the last-named said the process does not work with a soln. of aluminium sulphate. L. P. Cailletet obtained aluminium amalgam by connecting an aluminium wire with the negative pole of a battery and dipping it into mercury covered with acidulated water; M. Krouchkoll added that if aluminium and iron be both connected with the negative pole of a battery, and similarly treated, an amalgam of the two metals is formed. A. Roger electrolyzed a soln. of an alkali aluminate with an anode made from a mixture of alumina and carbon, and a mercury cathode.

According to C. Tissier, aluminium is made more electropositive by amalgamation, for, said J. Klaudy, it precipitates far more positive metals from soln. C. M. van Deventer found that in neutral and alkaline soln., unlike aluminium, it is more positive than zinc; and, added J. W. Richards, its reactivity approaches that of the metals of the alkaline earths. R. Kremann and R. Müller measured the electromotive behaviour of aluminium mercury alloys; L. Kahlenberg and J. A. Montgomery studied the effect of amalgamation on the potential of aluminium (*q.v.*); and alloys of aluminium with copper, zinc, or nickel. The amalgam very quickly loses its lustre in air, and is readily oxidized to alumina; the growth of the oxide is so fast that it has some resemblance to the so-called Pharaoh's serpents. The surface oxidation protects the portion underneath so that it takes may be 24 hrs. for the aluminium to oxidize completely. If the amalgam be warmed and agitated in air, more or less anhydrous alumina is formed, and it is coloured reddish owing to the simultaneous formation of a little mercuric oxide. M. Krouchkoll said that a mixed amalgam of iron and aluminium oxidizes more slowly in air than aluminium amalgam. Observations on this subject have been made by C. Tissier, J. Klaudy, C. M. van Deventer, L. B. Baille and C. Fèry, G. le Bon, W. J. Humphreys, A. Cossa, W. Ramsay, C. Jehn, H. Heuze, M. Robin, E. O. Erdmann, J. Schumann, P. Spica, etc.—*vide supra*, the chemical properties of aluminium. Aluminium amalgam decomposes water at ordinary temp. The reaction has been studied by J. B. Cohen and W. R. Ormandy, G. le Bon, C. Reichard, P. Spica, L. B. Baille and C. Fèry, C. M. van Deventer, A. Cossa, J. Klaudy, L. Hugounenq, E. Kohn-Abrest and co-workers, O. Mohr, H. Wislicenus, P. A. E. Richards, V. Zunino, H. Henze, E. O. Erdmann, F. Mylius and F. Rose, V. Biernacky, P. R. Jourdain, etc.—*vide supra*. According to J. Klaudy, acids readily attack aluminium amalgam, and, added H. Wislicenus, even acids so dil. that they are without action on aluminium. C. Tissier, L. B. Baille and C. Fèry, L. P. Cailletet, C. M. van Deventer, and E. Kohn-Abrest have studied this reaction; nitric acid, which scarcely affects aluminium *en masse*, dissolves out the aluminium from the mercury. L. B. Baille and C. Fèry state that aluminium amalgam is attacked by a soln. of potassium hydroxide, forming potassium aluminate. The reducing action of aluminium amalgam on nitrates and nitrites has been studied by J. B. Cohen and W. R. Ormandy; on alkali chromates, dichromates, and ferricyanides by C. M. van Deventer; and on potassium permanganate by J. Klaudy. F. W. Bergstrom found that amalgamated aluminium reacts with sodamide in liquid ammonia soln. to form a definite crystalline compound, **sodium tetramido-aluminate**, $Na\{Al(NH_2)_4\}$ or $Al(NH_2)_2.NHNa.NH_3$, which loses one mol. of ammonia on heating in a vacuum above 90°, forming

$Al(NH_2)_2.NHNa$. The actions of potassamide on amalgamated aluminium and on magnesium are analogous in character. A soln. of sodium in liquid ammonia reacts with amalgamated aluminium to form the same compound. The mercury does not play an essential part in the reaction. J. B. Baille and C. Fèry state that if antimony amalgam be mixed with aluminium amalgam, small crystals of antimony are formed on the surface; the aluminium then oxidizes so that the mercury is freed from both metals. This recalls the action of lead on a molten alloy of tin and aluminium which results in the expulsion of the aluminium. The action of aluminium amalgam on alcohol has been studied by H. Wislicenus and co-workers, D. P. Konowaloff, W. Tischtschenko, and J. Klaudy; on alkyl iodides, by H. Wislicenus, H. Fleck, etc. C. Radziewanowsky used the amalgam in the synthesis of aromatic hydrocarbons. The energetic reducing action of the aluminium couple on organic compounds has been studied by H. Wislicenus and co-workers, J. B. Cohen and co-workers, F. H. van der Laan, J. Klaudy, A. Lieben, M. Hanriot and A. Kling, H. F. Hunt and L. J. Steele, etc. E. Kohn-Abrest and co-workers found aluminium amalgam precipitates tannin and many alkaloids—nicotine, quinine, cocaine, etc., from soln.

§ 8. The Occurrence of Aluminium Oxides

Crystalline alumina occurs in nature as the mineral **corundum**, *corindon*, or *adamantine spar*. There are three main varieties distinguished by the structure, and by the degree of purity. (1) The transparent or translucent gem-stones named according to their colours—the true or oriental *ruby* is red varying in tint from pale rose to carmine-red, brownish-red, and bluish-red—the most prized variety is said to be pigeon's blood-red. The red colour is attributed to the presence of a little chromic oxide. The *sapphire* varies in colour from a pale blue to a deep indigo-blue. The paler varieties are sometimes described as feminine in contrast to the deeper and richer varieties called masculine. "Oriental" is sometimes prefixed to the name of the corundum gem-stones to distinguish them from other minerals possessing the same colour—*e.g.* the oriental topaz or yellow sapphire is yellow; the oriental emerald is green; and the oriental amethyst or violet-ruby is purple -the true amethyst is a variety of quartz. A variety of sapphire having a stellate opalescence when viewed in the direction of the vertical axis of the crystal is the stellate or asteriated sapphire. The six-rayed star reflected from the basal plane is due to the presence of numerous thin twin-lamellæ in the mineral. (2) Common *corundum* is transparent with no pronounced colour—for the tint varies from blue to grey, brown, or black. (3) *Emery*, a kind of granular corundum mixed with more or less magnetite or hæmatite.

The sapphire, *σάπφειρος*, of Theophrastos,[1] the *saphiros* of Pliny and of the ancient Greeks and Romans, were the *lapis lazuli* of the present day. It is, however, possible that the ancients included other minerals in the term, because Pliny said that the best purple sapphires come from Median. The origin of the term "sapphire" is not known; C. A. S. Hofmann said that it is a Grecian word taken from Island of Sapphirine in the Arabian Sea, but C. C. von Leonhard believed that the island was named after the mineral, and that the term is of Semitic origin; while S. Fränkel assumed that although the word is employed by Moses (Exodus, **24.** 10), it was imported into the Semitic language. Emery is the *Armenian whetstone*, or the *ἀκόνη ἐξ ἀρμενίας* of Theophrastos; the *smiris*, or *σμυρίς*, of Dioscorides; the *naxim* (from Naxos) of Pliny; the *smiris* of G. Agricola; and the *smergel* or *smirgel* of J. G. Wallerius. In 1609, A. B. de Boot defined the sapphire, asteria or sel gemma, ruby, and smiris. The similarity in the crystalline form led J. B. L. Romé de l'Isle to suggest the identity of these minerals, and R. J. Haüy placed the ruby and sapphire into one class which he named *télésie*, from *τέλεως*, perfect, but he regarded smirgel as *fer oxydé quartzifère*, and corundum as *un substance terreux.* S. A. Papavasiliou described the deposits at Naxos. T. Bergman analyzed sapphire and found Al_2O_3, 58; SiO_2, 35; CaO, 5; Fe_2O_3, 2; R. Chenevix also reported 5-7 per cent. of silica in sapphire, ruby, and corundum. M. H. Klaproth supposed that in addition to alumina, corundum and sapphire contained a new earth; S. Tennant showed that emery from Naxos is largely composed of alumina, and H. Rose stated that any silica found in the analysis of corundum is derived from the agate mortar used in the grinding. Numerous analyses have been made by J. L. Smith, K. Pfeil, A. Terreil, and others. The following are by J. L. Smith:

	Al_2O_3	Fe_3O_4	CaO	SiO_2	H_2O
Sapphire, India	97·51	1·89	—	0·80	—
Ruby, India	97·32	1·09	—	1·21	—
Corundum, India	93·12	0·91	1·02	0·96	2·86
Corundum, Nicaria	87·52	7·50	0·82	2·01	0·68
Emery, Naxos	68·53	24·10	0·86	3·10	4·72
Emery, Samos	70·10	22·21	0·62	4·00	2·10

The best rubies are found in clays and river sands at Mogok in Upper Burma; a less important locality occurs in the Sagyin Hills, Mandalay, also in Upper Burma. First-class rubies occur in the Capelan Mountains near Syriam (Pegu Ava). Less valued rubies are found in the provinces of Chantabun and Krat in Siam; at Bilin and Merowitz (Bohemia), and in the sand of the River Expailly (Auvergne). There are ruby mines in Badakshan on the Upper Oxus; and in Ceylon. The American localities are Newton (New Jersey), Lownes County (Georgia), Macon County (North Carolina), etc. Blue and star sapphires are brought from Ceylon; they have also been found near Simla Pass (Himalaya Mountains). The deposits of green and yellow sapphires in Central Queensland have been described by B. Dunstan. T. H. Holland has described the corundum deposits of India; J. Morozewicz, Russia; F. Zirkel, Austria; G. A. F. Molengraaf, South Africa; J. H. Pratt, United States; A. Lacroix, France; M. F. Heddle, Scotland; J. W. Retgers, Holland; etc. The emery deposits of Asia Minor and of the Grecian Archipelago have been described by J. L. Smith and A. Hänig, and those in the United States, by J. H. Pratt.

Bluish crystals occurring in some meteorites—F. Wöhler, E. Cohen, and E. Weinschenk—are thought to be crystallized alumina or corundum. It was supposed by A. A. Julien, T. M. Chatard, etc., that corundum was not primarily a pyrogenic mineral, and its presence in igneous rocks was attributed to accidental inclusions. The work of J. Morozewicz, and A. Lagorio has shown that corundum is of igneous origin, for it and spinel are among the first minerals to separate from soln. of alumina in molten basic glasses. They conclude:

(1) When the magma is a calcium-sodium-potassium silicate, alumina held in soln. by such a magma will separate out as corundum, except when the ratio of the alumina to the other bases is more than 1 : 1 and the ratio of the silica is less than six. (2) If magnesia and iron are present in the magma thus composed, corundum will not form unless there is more than enough alumina to unite with the magnesia and iron. (3) When the magma is composed of a magnesium silicate without excess of magnesia, all the alumina held by such a magma will separate out as corundum. (4) Where there is an excess of magnesia in the magma just described, this excess will unite with a portion of the alumina to form spinel, and the rest of the alumina will separate out as corundum. (5) Where there is chromic oxide present in a magma composed essentially of a magnesium silicate (as the peridotite rocks) and only a very little alumina and magnesia are present, these, uniting, separate out with chromic oxide to form the mineral chromite, and no corundum or spinel is formed. (6) When peridotite magmas contain, besides the alumina, oxides of the alkalies and alkali earths, as soda, potash, and lime, a portion of the alumina is used in uniting with these oxides and silica to form feldspar. (7) There is a strong tendency for the alumina to unite with the alkali and alkali-earth oxides to form double silicates like feldspars, whether such silicates form the chief minerals of the resulting rock or are present only in relatively small amount. There is, however, but little tendency for the alumina to unite with magnesia to form double silicates when the magma is a magnesium silicate.

In addition to colloidal alumina,[2] there are three possible hydrated forms of this oxide:

$$O\begin{cases}Al{=}O\\Al{=}O\end{cases}$$

Corundum- Al_2O_3

$$O\begin{cases}Al{=}(OH)_2\\Al{=}O\end{cases}$$

Diaspore- $Al_2O_2(OH)_2$

$$O\begin{cases}Al{=}(OH)_2\\Al{=}(OH)_2\end{cases}$$

Bauxite- $Al_2O(OH)_4$

$$Al{\equiv}(OH)_3$$

Gibbsite- $Al(OH)_3$

Clays, idealized by the formula $Al_2O_3.2SiO_2.2H_2O$, and nontronite idealized by $Fe_2O_3.2SiO_2.2H_2O$, may be regarded as the end-products of the weathering of felspathic rocks in the temperate climes, but in tropical and subtropical countries the process is said to extend further; the aluminosilicates are more completely decomposed, for aluminium and ferric hydroxides appear to be the end-products. It is not clear how the relatively small difference of temp. between temperate and tropical climes can produce such a difference in the decomposition products in aluminosilicate rocks. The deposits of red earths and soils, called by F. Buchanan (1807) *laterites*—from *later*, a brick or tile—found in India, Hawaiian Islands, Rhodesia, French Guinea, West Australia, Mozambique, etc., are mixtures of clay, silica, hydrated ferric and aluminium oxides, etc. Like clays (*q.v.*) they may be found *in situ*, or they may have been transported by streams of water, and deposited elsewhere. During the leaching, the laterite may have been freed from certain extraneous matters, and contaminated with others. Analyses of laterites have been reconstructed to show that when an allowance has been made for the accompanying quartz, and clay, the contained water agrees with the assumption that the residue is of the bauxite type mixed possibly with some gibbsite, diaspore, and limonite. As emphasized by C. O. Swanson, there is no sharp line of demarcation between bauxite and laterite; and he regards them as a peculiar type of clay. A. Luz, after reviewing the evidence on the formation of laterites, concluded that the different stages in the weathering of the basic aluminosilicates are: (i) the formation of colloidal aluminium silicate; (ii) colloidal alumina and silica; (iii) crystalline hydrargillite; and (iv) crystalline diaspore.

According to E. Dittler and C. Doelter, commercial bauxites are to be regarded as rocks since they are compounded of various minerals—diaspore, gibbsite, and the amorphous aluminium hydroxide bauxite, together with intermixed limonite, hæmatite, and clay. Such mixtures have been named *diasporite*, *gibbsitite*, or *bauxitite*, according to the predominance of one or other of these constituent minerals. The two former are referred to as *crystalloidal alumolites*, and the latter as *colloidal alumolites*.

The weathering theory of the formation of bauxite is employed to explain deposits in Germany,[3] Hungary,[4] Spain,[5] British Guiana,[6] at Auvergne (France),[7] Ireland,[8] Arkansas,[9] South Africa,[10] etc. The deposits in Auvergne are derived from gneiss rocks; those in Hesse, Ireland, and Australia from basaltic rocks; and those in Arkansas from syenitic rocks. The French bauxites are associated with cretaceous rocks, and they have been regarded as deposits from hot waters carrying alumina in soln.[11] The Georgia-Alabama bauxite field [12] is also assumed to have been deposited from lagoons.

In 1821, P. Berthier [13] analyzed *alumine hydratée des Beaux*, near Arles, Department Bouches-du-Rhône, and found Al_2O_3, 52·0; Fe_2O_3, 27·6; H_2O, 20·4 per cent. and a trace of chromic oxide. A. P. Dufrénoy named this product *beauxite* and classed it with gibbsite, although he recognized that the composition of the two substances is very different. H. St. C. Deville called it **bauxite.** J. F. L. Hausmann regarded it as a mixture of hydrated alumina and ferric oxide, and represented its composition by $Al_2O_3.2H_2O$, intermediate between gibbsite and diaspore. A. Flechner named the deposit at Wochein (Styria), *wocheinite*; and C. Adam, the deposit at Cliache (Dalmatia), *cliachite*—*vide infra*, colloidal aluminium hydroxides. Bauxite is a mixture of hydrated aluminium oxides in which the molar ratio $Al_2O_3 : H_2O$ varies from 1 : 1 to 1 : 3. The old standard formula $AlO(OH)_4$ thus belongs to an idealized compound. The colour varies from white to pale cream or red and dark brown; hence *ferruginous bauxites* are red-coloured, and *non-ferruginous bauxites* are white or cream-coloured. Bauxite usually has a concretionary structure, and the size of the concretions distinguishes between *pebble ore*, and *pisolitic ore*—πίσον, a pea, and *oölitic ore*—ὠόν, an egg. The *amorphous ore* has scarcely any trace of the concretionary structure, and it may be soft and friable, or hard and compact.

The bauxite produced in the *United Kingdom* comes from Ireland, where it is found associated with the pisolitic iron ores and laterites at Clegnagh, Essatholam, Tuftarney, Glenarm, Irish Hill, Straid, etc., in County Antrim. There is also a deposit at Killygreen, County Londonderry. The deposits have been described by G. A. J. Cole, E. Hull, and G. H. Kinahan. The bauxite lies next to the upper basalt unless, as is sometimes the case, a layer of lignite intervenes. The stratum of bauxite generally merges into iron ore running 30–60 per cent. Fe_2O_3. The upper part of the iron ore contains small nodules of iron oxide the size of peas. These gradually diminish in size as the stratum merges into bauxite clay. The bauxite varies in thickness from 2 ins. up to 2 ft.; under the bauxite is a layer of bole 2 ft. to 10 ft. thick; this is followed by a stratum of slate-coloured clay called lithomarge, 20 ft. to 30 ft. thick. The lithomarge contains SiO_2, 49·75; Al_2O_3, 29·88; Fe_2O_3, 6·61; H_2O, 5·48 per cent. There are intrusive dykes here and there. Bauxite mining began in Ireland in 1871. The alumina in Irish bauxite is almost all soluble in sulphuric acid, while about 8 per cent. of the alumina in French bauxite is insoluble. The dark bluish variety of bauxite has usually the highest proportion of alumina. The dried and ground bauxite from Irish Hill had the following percentage composition:

	Al_2O_3	Fe_2O_3	H_2O	SiO_2	TiO_2	CaO	MgO
1st quality . .	53·83	1·57	29·27	8·67	5·80	0·62	0·13
2nd quality . .	52·00	4·57	24·00	12·00	6·20	0·79	0·20
3rd quality . .	46·13	15·14	23·39	10·40	4·21	0·18	0·26

With K_2O respectively 0·01, 0·02, and 0·04; Na_2O, 0·00, 0·02, 0·04; H_2SO_4, 0·07, 0·07, and 0·10; mere traces of phosphoric oxide, and hygroscopic moisture lost at 100°, 7·50, 0·90, and 0·85.

In *France*, there is a band lying almost parallel with the Mediterranean in the departments of Hérault, Bouches-du-Rhône, Var, and Alpes-Maritimes. The bauxite from Villeveyrac (Hérault) is white and contains a high proportion of alumina with but little iron and silica. It is used in the manufacture of aluminium salts. The red-banded bauxite of Baux (Arles) contains about 60 per cent. of alumina. It is used in the manufacture of aluminium. The dark red bauxite of Thoronet and Luc (Var) has a splintery or conchoidal fracture. Valuable deposits of bauxite occur in *Italy* near Abruzzi and Tamnium. F. Kerner-Marilaun studied the bauxite deposits of the East Adriatic. In *Jugo-Slavia*, bauxite occurs in Dalmatia, Rammlajane, Blaca, Konjsko, and Kalun. In *Rumania*, there are deposits in the Bihar Mountains, and at Fata Oarza. A siliceous bauxite has been reported from Catalonia in *Spain*. A deposit of high-grade bauxite has been found on Mount Ejuanema on the *Gold Coast*. Many laterite deposits in *India* were highly aluminous. The richest deposits are in the Baihir plateau, and near Katni in the Central Provinces. Bauxite also occurs near Chota Nagpur, Sarguja, Bihar and Orissa; in Bhopal and Rewah, Central India; Satara, Bombay; and in the Madras Presidency. Deposits have been found in *Australia*—various parts of Queensland, and New South Wales; in Yankabilla, South Australia; and on the Darling Range and Eastern Goldfield of West Australia. The chief occurrences in the *United States* are in Arkansas, Georgia, Alabama, and Tennessee – perhaps 80 per cent. of the output being obtained from mines in Arkansas. Deposits occur in *Dutch Guiana*, *French Guiana*, and *British Guiana*.

Numerous analyses of bauxites have been reported.[14] A selection is shown in Table V. According to F. Laur, the average alumina in thousands of shipments

of French bauxites was 66–69 per cent.; the sum of the three variables, water, silica, and ferric oxides, approximated to 27 per cent.; and the accessory substances averaged 3 to 4 per cent. A. Cobenzl, and M. Ragg attributed the blue colour to the presence of colloidal ferrous oxide. Titanium is almost invariably present, and when not reported, it may be assumed that the amount has not been determined; its amount ranges usually from 1 to 10 per cent., although higher proportions are sometimes found. According to T. L. Watson, the amount of titanium is usually highest in the pisolitic ores and lowest in structureless bauxite. A. von Liebrich, and J. Lang state that it occurs as free titanic oxide, or ferric titanic oxide. Silica is always present in bauxites in amounts varying from one to several per cent.; it is probably present as clay and quartz. H. Arsandaux said that the silica in bauxite is more often present as clay than as quartz ; and, in agreement with P. Berthier, the iron is present as oxide rather than as hydroxide. The low-grade bauxites with, say, 30 to 35 per cent. silica may be usually regarded as bauxitic clays. It may be added that a series of natural products can be obtained passing by insensible gradations from corundum through bauxites, laterites, clays, arenaceous clays, on to silica ; or from corundum, through the ferruginous clays, on to hæmatite. D. C. Wysor has discussed the nature of the bauxitic or diaspore clays of Missouri and Arkansas. Common impurities, not always reported in analyses because usually present in but small proportions, are compounds of calcium, magnesium, potassium, and sodium—phosphates, sulphates, and carbonates. H. St. C. Deville found minute quantities of vanadium to be contained in some samples of bauxite. There are also present traces of molybdenum, tungsten, etc., not separated from the alumina by the usual precipitating agents. R. L. y Gamboa found gallium in bauxite.

A. Lacroix said that under the microscope, bauxite is *absolument colloïdes;* and F. Cornu has described the gel characteristics of *die isotropen Substanzes des Bauxites.* H. Stremme discussed the colloidal nature of many of the aluminosilicates. F. Slavik gave 1·60–1·61 for the refractive index of bauxite. E. Löwenstein measured the vap. press. of bauxites.

R. S. Bayer obtained a residual soln. after removing all the known elements, and reported that it contained a new element which he named *bauxium.* The soln. on spectroscopic examination was later shown to contain a mixture of the elements just named along with traces of lead, copper, bismuth, etc. A mixture of ammonium vanadate and tungstate gives all the reactions which R. S. Bayer thought to be characteristic of bauxium.

§ 9. Aluminium Oxides

J. E. Ashby [1] reported that when alumina is heated red-hot, and quenched in alcohol, it becomes black; and claimed that the black colour is not due to carbon from the decomposition of the alcohol because it also appears when the alumina is quenched in conc. aq. ammonia. He suggested the black colour is due to the formation of a suboxide. The object of H. St. C. Deville in working on aluminium was to prepare **aluminium suboxide,** AlO, analogous to ferrous oxide, FeO. He tried to make the subchloride, $AlCl_2$, by passing the vapour of the trichloride, $AlCl_3$, over the metallic powder formed by reducing alumina with potassium. He obtained fine globules of aluminium embedded in a mass of potassium aluminium chloride, $AlCl_3.KCl$, but no subchloride. His attention was thence diverted to the metal, and he did not make any further experiments on the suboxide. No aluminium suboxide has yet been unequivocally demonstrated as a chemical individual. G. A. Kenngott said that if calcined and powdered diaspore, corundum, or artificial alumina be moistened with water, and heated in a reducing flame, a suboxide is produced; and E. Beetz said that in the electrolysis of soln. of sodium chloride with aluminium electrodes, the cathode becomes covered with a black layer of what he regarded as aluminium suboxide, analogous to magnesium suboxide obtained under similar conditions. A. Duboin stated that by igniting an intimate mixture of a mol of alumina with four gram-atoms of aluminium at one point, the whole mass becomes incandescent, and aluminium suboxide, AlO, is formed. E. Kohn-Abrest claimed to have made a pearl-grey powder by heating aluminium in air to 1000° for about an hour; he said that the product is homogeneous, and gives hydrogen when treated with hydrochloric acid; analyses correspond with Al_4O_3 or Al_2O. J. Pionchon claimed to have made a suboxide, Al_6O_7, or $3Al_2O_3.Al_2O$, by heating aluminium in the oxy-hydrogen blowpipe flame fed with comparatively little oxygen. The grey powder remaining after the brilliant combustion, dissolves partially in hydrochloric acid evolving hydrogen, and leaving a residue of alumina. These experiments agree with the assumption that the grey powder is a mixture of alumina and finely divided aluminium. According to C. Winkler, a mol of alumina mixed with a gram-atom of magnesium and heated in a current of hydrogen gave a black powder which was assumed to be a mixture of 40 per cent. of the suboxide, AlO, with undecomposed alumina, and magnesia.

According to E. Grobet,[2] on adding sodium hydroxide to dil. soln. of aluminium nitrate, insoluble aluminium hydroxide, and soluble sodium metaluminate, and sodium ortho-aluminate are successively formed. When dil. soln. of aluminium sulphate or chloride or potash alum are used, aluminium hydroxide, basic sodium aluminate, $Al(ONa)_3.Al(OH)_3$, and sodium ortho-aluminate are formed successively. Conc. soln. of aluminium chloride, nitrate, or sulphate produce under the same treatment a basic salt of the type, $AlX_3.Al(OH)_3$, which is followed by the hydroxide, metaluminate, and ortho-aluminate. Conc. soln. of potash alum yield a basic salt, $Al_2(SO_4)_3.2Al(OH)_3$, aluminium hydroxide, a basic aluminate, $Al(ONa)_3$, $Al(OH)_3$, and the ortho-aluminate. In preparing **hydrated alumina,** $Al_2O_3.nH_2O$, an alkali hydroxide is added to a soln. of an aluminium salt; or, preferably, aq. ammonia is used because the precipitate is insoluble in an excess, and it introduces no non-volatile constituent into the system. The slimy mass is difficult to wash. To facilitate the washing, it is best to conduct the precipitation with boiling soln. and wash the hot precipitate with a hot soln. of ammonium nitrate or chloride. The ignition of the washed precipitate furnishes alumina.

According to J. J. Berzelius, and C. F. Bucholz, if ammonia be added to a soln. of alum a basic sulphate will be formed. H. Krämer said not if the alum soln. be added to the ammonia; but G. C. Wittstein and S. von Thielau still found the precipitate contained sulphates. J. J. Berzelius precipitated a hot soln. of alum free from iron, with alkali carbonate, digested the precipitate with the mother liquid to decompose what he regarded as a basic sulphate, washed it thoroughly with water; dissolved it in hydrochloric acid; re-precipitated with ammonia, and ignited. J. von Liebig treated a soln. of alum with barium chloride, evaporated the filtrate to dryness, and washed the chlorides of barium and potassium from the ignited product by means of water acidulated with hydrochloric acid. G. Ekmann and O. Petterson added barium chloride to a soln. of potash alum, and precipitated the hydroxide by adding ammonia to the filtrate; the washed precipitate was dissolved in hydrochloric acid and again precipitated with ammonia. After a third treatment they found the precipitate to be quite free from alkali.

These processes are not sufficiently economical to be worked on a large scale. One of the easiest methods of making alumina is that recommended by J. L. Gay Lussac, namely, to ignite at a red heat ammonia-alum which has been dehydrated and partially decomposed at a low temp. A little sulphuric acid still remains with the alumina. C. Brunner showed that, if necessary, this can be removed by moistening the mass with a soln. of sodium carbonate, drying and again igniting. When the product is washed with water, the sulphuric acid is removed as sodium sulphate. The alumina is now contaminated with a little sodium hydroxide which cannot be removed by washing. If potash-alum be ignited, most of the potassium sulphate is washed out before the last ignition. F. Wöhler recommended igniting a mixture of aluminium sulphate with 20 per cent. of sodium carbonate, and afterwards washing the sodium sulphate from the alumina. M. Buchner has suggested several methods of making granular hydrated alumina.

The preparation of alumina from bauxite or aluminous earths.—The bauxite used in the preparation of aluminium must be freed from the contained silica, titanic oxide, and ferric oxide, if the aluminium is to be obtained of the required degree of purity. The Irish bauxite containing on the average: Al_2O_3, 56; Fe_2O_3, 3; SiO_2,12; TiO_2, 3; water, 26 per cent., has been employed for this purpose; but, according to F. R. Low, it is considered uneconomical to work bauxite with over about 3 per cent. of silica. The French bauxite may have up to 75 per cent. alumina. The process of purification involves two main operations: (i) the preparation of sodium aluminate and the soln. of this salt to separate it from the ferric oxide; and (ii) the precipitation of hydrated alumina from this soln. At Salindres, where H. St. C. Deville's aluminium process was employed, alumina was obtained from bauxite by L. le Chatelier's process.

An intimate mixture of powdered bauxite and 39 per cent. sodium carbonate, is heated in a reverberatory furnace; when the reaction is completed, the sodium aluminate is leached from the insoluble ferric oxide with a dil. soln. of aluminate from the preceding charge. The conc. liquor is treated with carbon dioxide to precipitate the alumina. The furnace charge is again washed with water, and the dil. soln. is employed for leaching the next charge. The liquor is agitated while it is being treated with carbon dioxide; the precipitation occupies about 5-6 hrs. The soln. of sodium carbonate is decanted from the alumina, and evaporated to furnish most of the alkali carbonate required for the next charge of bauxite. The moist alumina is treated in a centrifugal washer to remove the adherent sodium carbonate, washed with water, and again centrifuged. The product contains 47·5 per cent. of alumina, 50·0 per cent. of water, and 2·5 per cent. of sodium carbonate.

According to G. and F. Löwig, a soln. of alkali aluminate can be precipitated with hydroxide of calcium, strontium, barium, or magnesium, forming the alkali hydroxide and a mixed precipitate of hydrated alumina and lime, strontia, baryta, or magnesia. The precipitate is washed by decantation and divided into two portions—one is dissolved in hydrochloric acid, and the other made into a mush with water. The latter is gradually added to the former until very little alumina remains in soln. Hydrated alumina is thus precipitated, and the chloride of the alkaline earths or magnesia passes into soln.

Instead of precipitating the alumina from the aq. soln. of sodium aluminate by treatment with carbon dioxide, in **C. J. Bayer's process** [3] the hydrated alumina is precipitated by adding hydrated alumina itself. In 1833, P. A. von Bonsdorff showed that a sat. soln. of gelatinous aluminium hydroxide in potash-lye, slowly deposits crystals of gibbsite, when kept in a closed vessel for some days. A. Mitscherlich, and L. Péan de St. Gilles showed that aluminium hydroxide becomes sparingly soluble in acids when it has been allowed to stand for some time; and M. Berthelot attributed this to *une condensation moléculaire de l'alumine.* The hydrated alumina precipitated in C. J. Bayer's process is in the crystalline form, and C. J. Bayer, and A. Ditte assumed that two varieties of hydrated alumina are involved—the gelatinous and the crystalline; and that the crystalline form is far less soluble than the gelatinous. A soln. sat. with the gelatinous hydroxide must therefore be supersaturated with respect to the crystalline form; consequently, if the soln. of the gelatinous hydrate be seeded with the crystalline hydrate, precipitation will occur. F. Russ has adopted a similar explanation; he called the more soluble and less stable form the α-hydrate, and the crystalline, less soluble and more stable form the β-hydrate. The precipitation of the latter from a soln. of the former depends on the rate of transformation of the α- to the β-hydrate; and this is favoured by hydroxyl ions. F. Russ measured the solubility of the β-hydrate (mols Al_2O_3) in soln. of sodium hydroxide of different conc. (mols Na_2O per 100 mols of H_2O), at 19°, as shown in Fig. 47. There is a rapid increase in solubility with increasing conc. of alkali for soln. with over 5·2 mols Na_2O per 100 mols of water. He also found the times at which precipitation occurred with soln. of the gelatinous α-hydrate in soda-lye of different conc., between 19°–22°:

Sp. gr. of lye .	1·013	1·063	1·111	1·173	1·240	1·304	1·391	1·530	1·570
Time (days) .	6	½	½	3	1	1	2	6	38
	Small colloidal			Large				Small	
				Crystalline					

In the second and third cases the precipitate became crystalline in about 10 days. After allowing the mixtures to stand 22 weeks, at about 20°, the amounts of hydrated alumina precipitated from soln. of different conc. are indicated in Fig. 48. The

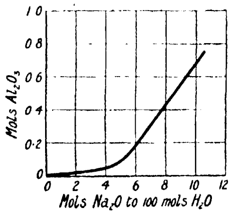

FIG. 47.—Solubility of Alumina in Solutions of Sodium Hydroxide.

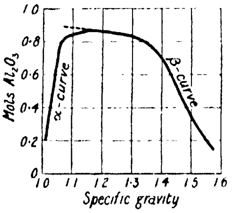

FIG. 48.—Precipitation of Alumina from Solution in Sodium Hydroxide.

β-curve is the reciprocal of the solubility curve; the α-curve is not so easily interpreted because of the transformation of a certain proportion of the α- into the β-hydrate. The curve also shows that the maximum precipitation occurs with soln. of sp. gr. approximately 1·2.

J. Sutherland has described the process employed at Larne Harbour. The bauxite is ground, calcined, and then agitated under press. with a conc. soln. of sodium hydroxide—sp. gr. 1·45. Sodium aluminate passes into soln., while the ferric oxide, silica, and titanic oxide remain undissolved. The soln. is diluted to a sp. gr. 1·23, and passed through filter presses, and then through wood-pulp supported on ⅛th in. mesh sieves. The liquor is then ready for the precipitation. This is effected by agitating the liquor in tanks for about 36 hrs. with some of the aluminium hydrate from the preceding charge. The precipitation continues until the molar ratio $Al_2O_3 : Na_2O$ is about 1 : 6. In practice about 70 per cent. of the alumina in the soln. of sodium aluminate is precipitated. The mixture is allowed to settle for a short time, the clear liquor is run into weak liquor tanks, and the slurry of hydrated alumina is pumped into filter presses where the alumina is washed, dried, and calcined to about 1100°. Enough hydrated alumina is left in the precipitation tank to begin the decomposition of the next charge. The liquor is then conc. by evaporation up to a sp. gr. 1·45 and used for extracting alumina from the next charge of bauxite.

C. M. Hall proposed to extract the alumina from bauxite by heating the powdered mineral with a soln. of calcium hydroxide and sodium carbonate or hydroxide under high press. He claimed that calcium phosphate, carbonate, and silicate remain undissolved while sodium aluminate passes into soln. The hydrated alumina is then precipitated in the usual way. F. R. Lowe described the extraction of alumina by this process. The Chemische Fabrik Greisheim-Elektron found that there is no need to work at a high press. if a temp. of 180°–200° be employed with potash-lye, or 350°–500° with soda-lye. F. Curtius, and F. Kunheim have suggested modifications of the process for obtaining a soln. of sodium aluminate from bauxite. To separate alumina of a high degree of purity from the soln. obtained by treating bauxite with sodium hydroxide, J. A. Bradburn and J. D. Pennock proposed a kind of fractional precipitation of hydrated alumina with carbon dioxide or calcium hydroxide. E. Everhart agitated the disintegrated bauxite ore with a deflocculating agent, such as sodium hydroxide soln., until the clay matter is all in suspension; granular bauxite remains. R. S. Sherwin leached a sintered mixture of bauxite or clay with lime and a sodium compound. Silica is precipitated when the soln. is heated under press.

Fused sodium chloride does not react with bauxite, but if steam be present sodium aluminate is formed and hydrogen chloride evolved. This process was recommended by R. A. Tilghmann.[4] A proposal has been made by J. H. C. Behnke to obtain alumina from bauxite by calcining a mixture of the mineral with sodium sulphate, carbon, and ferric oxide. According to F. Lauer, it is advantageous to use a little sodium carbonate with the sulphate. The frit is leached with water when sodium aluminate and sulphate pass into soln. The hydrated alumina is precipitated in the usual way; the insoluble residue has to be roasted and fused over again.[*] M. Platsch, K. Lieber, A. Clemm, and D. A. Peniakoff have suggested modifications of this process. E. Collett fused the bauxite with lime and a little sodium carbonate, treated the powdered product with a soln. of sodium hydroxide, and precipitated the alumina by carbon dioxide. R. von Wagner boiled bauxite in a soln. of sodium sulphate whereby hydrogen sulphide was evolved and a soln. of sodium aluminate formed.

[*] According to H. S. Blackmore, phosphorus, selenium, and tellurium can be removed from bauxite and other refractory minerals by passing the vapour of carbon disulphide or hydrocarbons over the heated mineral. C. F. Claus prepared a soln. of alkali aluminate by making briquettes with a mixture of bauxite or bauxite and hydrated alumina with sodium or potassium chloride; heating the briquettes in a continuous chamber kiln to 400°–500° in a current of heated sulphur dioxide, steam, and air whereby sulphates are formed, and hydrogen chloride evolved; and reducing the sulphate to sulphide by heating with water gas, carbon monoxide, or hydrogen. The alkali sulphide then reacts with the aluminate, forming alkali aluminate and evolving hydrogen sulphide. The product is then leached with water. C. M. Hall claimed to prepare pure alumina from bauxite by heating in a carbon-lined electric furnace a mixture of bauxite, carbon, and aluminium powder. The proportion of the latter is determined by the amount of ferric oxide, silica, and titanic oxide in the bauxite, and if the ferric oxide is low, some may be advantageously added. The reduced iron, silicon, and titanium form an alloy with the small portion of aluminium added. The alloy collects at the bottom of the furnace. The alumina remaining is powdered, and the metallic particles removed by a magnet.

In some cases, the bauxite has been digested with sulphuric acid and aluminium sulphate obtained from the soln. As R. Helmhacker[5] showed, some ferric sulphate is also formed. F. Lauer treated the soln. with zinc plates to precipitate the iron; J. W. and T. Chadwick and J. W. Kynaston used arsenious oxide; J. J. Hood and A. G. Salomon used stannic acid; C. Fahlberg, lead dioxide; J. W. Kynaston, manganese dioxide; J. Beveridge used antimonic acid or potassium ferrocyanide; C. V. Petraeus, and T. Robinson used sulphides of the alkalies or alkaline earths; and J. L. Kessler used phosphoric acid. M. Ducla treated the mixed iron and aluminium sulphates with a mixture of milk of lime and calcium carbonate, and separated the precipitated alumina from the ferric oxide by dissolution in soda-lye. A. Wacker described an electrolytic process of purification of aluminium salts. J. Morel treated bauxite with a mixture of sulphur dioxide, air, and steam below 800° so as to form the soluble sulphate, from which alumina was precipitated by sodium thiosulphate. A. Hurtur converted aluminium sulphate into alumina by ignition in hydrogen. A. L. Pedemonte heated the bauxite in a reducing atm., separated the reduced iron by electromagnets, dissolved the product in acid, evaporated to remove silica, etc.

Some native alum earths furnish a soln. of aluminium sulphate by simply leaching with water. *Alunite*—a basic potassium aluminium sulphate—is roasted between 800°-900°, and the product treated with sulphuric acid. The conc. soln. furnishes crystals of alum. J. Blumenwitz has described the process in detail. H. F. Chappel heated the alunite at a temp. high enough to volatilize the potassium sulphate, and form alumina. According to A. Mitscherlich, alum shales are roasted at a low temp. and then exposed to the atm. The pyrites are oxidized and sulphuric acid is produced, which forms aluminium sulphate. The latter is leached from the mass with dil. sulphuric acid—*vide infra*, alum. The process has been discussed by P. Guyot, F. Trögler, M. Vinck, A. H. Seger, K. W. Jurisch, etc. J. Webster transformed alum to alumina by heating a mixture of alum and pitch to about 250°; the product was mixed with dil. hydrochloric acid and made into briquettes with about 5 per cent. of carbon. The briquettes were heated in a current of steam and air; when leached with water, potassium sulphate passes into soln., and alumina remains behind. F. Jourdain fused leucite with lime, and extracted the mass with water to get the alkali aluminate into soln. The alumina was precipitated with carbon dioxide.

The preparation of alumina from cryolite.—J. Thomsen[6] worked up cryolite into alumina and sodium carbonate as indicated in connection with sodium carbonate —**2.** 20, 28. According to F. Lauterborn, cryolite is decomposed into aluminium and sodium fluorides when boiled with water. H. Bauer boiled a mixture of cryolite and calcium carbonate with water: $2Na_3AlF_6+3H_2O+6CaCO_3 \quad 2Al(OH)_3+3CO_2+3Na_2CO_3+6CaF_2$; the alkali carbonate and hydrated alumina form soluble sodium aluminate. H. St. C. Deville used a somewhat similar process at Javel. If steam be passed over molten cryolite at a red heat, C. A. Dorenius found that hydrogen fluoride is evolved and sodium aluminate, mixed with some fluoride, is formed. C. Pieper, and L. Grabau discussed the purification of soln. of aluminium fluoride. L. Schuch treated finely powdered cryolite with conc. soda-lye, and obtained sodium aluminate in soln., and sodium fluoride as a sediment. W. J. Williams, and L. Grognot discussed the conversion of the alumina in aluminium iron phosphate minerals into sodium aluminate.

The preparation of alumina from clays and other aluminosilicates.—A large field is open for the utilization of clay or other aluminosilicates, for the manufacture of aluminium. The cost of separating from alumina the dangerous impurity, silica, has prevented the many proposals from competing with bauxite as the cheapest raw material available. So important is bauxite to the aluminium industry that R. Sylvany[7] could say: "Without the discovery of important bauxite fields the alum and aluminate industries would not have developed, and the aluminium industry would not exist." If cheap methods of desilicifying china clays should ever be discovered, it will appear as if the availability of supplies of bauxite accelerated the growth of the aluminium industry along the path of least resistance. Many of the suggestions which have been made involve the treatment of the aluminosilicate with sulphuric acid, or with some heavy metal sulphate, and the soln. of aluminium sulphate finally produced is crystallized from the soln. as alum. The processes generally have been discussed by A. and P. Buisine, J. Bronn, H. Debray, M. Feigensohn, etc.; and by K. W. Jurisch in his *Die Fabrikation von schwefelsaurer Thonerde* (Berlin, 1894).

L. Grabau treated the clay, as free as possible from iron compounds, with dil. hydrofluoric acid, and obtained a soln. of aluminium fluoride—the silica is volatilized as silicon tetrafluoride. H. Pemberton and J. Spiller have discussed a process in which felspar is treated similarly with a mixture of sulphuric and hydrofluoric acids. A. Sobrero roasted the clay, free from iron and calcium compounds, mixed the powdered mass with conc. sulphuric acid, and heated it to about 70°, when aluminium sulphate was formed. This was extracted with water and the soln. treated with potassium sulphate for alum; P. Spence and co-workers added potassium chloride in place of the sulphate. H. Peterson used a modification of the process for lepidolite. F. Lauer roasted the material with iron pyrites to form sulphates which react with the clay, forming aluminium sulphate. This mixture is leached with water when the last-named salt passes into soln., and the basic iron sulphates are left as slime. The sulphate in soln. is converted into alum. R. Hasenclever and W. Helbig, H. Tanaka and T. K. Shikenjo, M. Buchner, M. de Lammine, F. W. Howorth, F. Gruy, H. Müller, M. Metcalf, A. Claude, W. H. Gossage, T. Richardson, etc., have described processes for extracting alumina from clay. When clay has been heated to 500°–600°, it is more readily attacked by acids than the original clay. J. Heibling made briquettes from a mixture of the clay with ammonium and potassium sulphates. After calcination at 270°-280°, the extract with water furnished alum. H. Müller heated a mixture of the clay with powdered calcspar, dolomite, or magnesite along with alkali hydroxide or carbonate, or a mixture of alkali sulphate and carbon. When the sintered mass is leached with water, a soln. of alkali aluminate and an insoluble alkaline earth silicate are formed. E. Fleischer, and F. Projahn used modifications of this process. L. Lossier fused the aluminosilicate with cryolite or fluorspar, and again with sodium chloride. The mass forms two layers—the upper one contains sodium chloride and aluminium fluoride, the lower one, sodium and calcium aluminosilicate. A. H. Cowles heated briquettes made from clay, sodium chloride, and charcoal in a stream of air and steam. The carbon keeps the mass porous and allows the gases readily to penetrate the mass. W. Gossage, and H. Grüneberg and J. Vorster failed to utilize this reaction with the charcoal omitted. A sodium aluminosilicate is formed, $2Na_2O.2SiO_2.Al_2O_3$; this is mixed with lime and heated in a rotary kiln: $2Na_2O.Al_2O_3.2SiO_2+4CaO=2Ca_2SiO_4+2Na_2O.Al_2O_3$. The sodium aluminate is soluble in water, and the calcium silicate can be used in the manufacture of hydraulic cement. In P. Miguet's process, clay, lime, and scrap iron, with a reducing agent, are heated in the electric furnace, forming silica, calcium aluminate, and ferrosilicon: $Al_2O_3.2SiO_2.2H_2O+Fe+4C+CaO=FeSi_2+4CO+CaO.Al_2O_3+2H_2O$. The lighter calcium aluminate floats on the regulus, and is tapped off, cooled, crushed, and leached with a soln. of sodium carbonate whereby sodium aluminate and calcium carbonate are formed: $CaO.Al_2O_3+Na_2CO_3=CaCO_3+Na_2O.Al_2O_3$. Aluminium hydroxide is obtained from the soln. in the usual way. The ferrosilicon is a marketable by-product C. E. Williams and C. E. Simms examined the process, but found that it is not profitable. S. D. Cheine heated a mixture of clay, baryta, and scrap iron, and treated the product in a similar way.

G. Levi, and E. Langguth, and M. Packard discussed the treatment of leucite, sodalite, and nephelite. If these aluminosilicates be heated under a press. of 16–20 atm. with a soln. of alkali hydroxides or carbonates, alkali aluminates are not formed, but the alkali silicate passes into soln., and alumina remains. The Aktieselskabet Höyangfaldene Norsk Aluminium Co., and D Tyrer heated to 1200° an intimate mixture of the aluminiferous material with lime and a little fluorspar as a flux. The cold mass was digested with a 10-15 per cent. soln. of sodium carbonate, and the alumina separated from the hot filtered soln. in the usual way. P. Askenasy and V. Gerber proceeded similarly, but used a mixture of baryta and lime and sodium chloride as a flux. The Aluminium Co. extracted the alumina from silicates, etc., in which the contained aluminium will form the volatile chloride when the ore is heated with a suitable chloride. G. Bergen and W. Kühne heated the clay with magnesium chloride, pyritic bituminous shale and iron filings, and collected the aluminium chloride which distilled off. A. L. Mond extracted the alumina with hydrochloric acid, etc. J. D. Gaté passed an electric current through a bath of sodium chloride at 1100°-1200°, in which the aluminium ore—say orthoclase—is immersed; the sodium which is formed partly reduces the silicate, forming soluble silicates and aluminates. These are withdrawn and dissolved in water. The precipitated alumina and silica are separated by the selective dissolution of the alumina in dil. soln. of sodium hydroxide.

M. Amono and co-workers treated blast furnace slag with hydrochloric acid; the soln. was diluted, and decanted from the precipitated silica: the alumina was precipitated with calcium carbonate and afterwards taken up with sulphuric acid. E. Raynaud heated aluminous material with sulphides of the alkalies or alkaline earths, or with a mixture of sulphate and carbon; the alkali salts are extracted with water. U. Pomilio crystallized potassium chloride from the hydrochloric acid soln. of leucite, and separated the alumina by electrolysis.

A soln. of sodium aluminate is formed as a by-product in Serpek's process (*q.v.*) for the fixation of nitrogen. Here, aluminium nitride is prepared by heating a mixture of bauxite and carbon to 1500°–1800°, in a stream of producer gas consisting mainly of carbon monoxide and nitrogen. When the resulting product is treated with soda-lye, ammonia and sodium aluminate are formed.

The formation of crystalline alumina (corundum).—Corundum crystals were first prepared by M. A. Gaudin[8] in 1837 by heating to a very high temp. a previously calcined and powdered mixture of alum and potassium sulphate, or alumina and potassium sulphide, contained in a crucible lined with carbon. Since then, the crystals have been obtained in many ways. These have been described generally by F. Fouqué and A. Michel-Lévy, L. Bourgeois, J. Morozewicz, S. Meunier, etc., J. Morozewicz classified the methods of synthesizing corundum, (i) Crystallization of molten alumina; (ii) crystallization from a molten flux; (iii) the decomposition of aluminosilicates at high temp.; and (iv) the decomposition of aluminium salts at a high temp.

(1) *The preparation of corundum directly from alumina.*—M. A. Gaudin obtained spheres with crystal facets, by melting alumina in the oxy-hydrogen blowpipe flame. E. S. Shepherd and G. A. Rankin[9] found that precipitated alumina acquired a crystalline structure by simple heating at about 200°. H. Moissan melted alumina in an electric furnace, and found, on cooling, that crystallization had taken place; if the alumina be mixed with chromic oxide, crystals of ruby are formed. The by-product obtained in the reduction of chromic oxide by aluminium in the thermite process contains minute rubies. The crystals of artificial ruby were described by A. des Cloizeaux, G. Melczer, F. Rinne, O. Mügge, J. Klaudy, etc. M. Buchner made the by-product into pottery. The mixture has the trade-name *corubin*. The crystals of alumina are also sometimes found in electric furnaces used in the preparation of aluminium. G. Döllner obtained corundum by heating a mixture of aluminium and boric oxide or chromic oxide by the thermite reaction; W. Hampe also obtained the crystals in preparing aluminium boride; W. Gintl, by reducing bauxite with carbon in an electric furnace; and J. W. Mallet, by reducing magnesia with aluminium at a high temp. A. Verneuil prepared artificial rubies in the form of spheroids having a diameter of 5 to 6 mm. and weighing 2·5 to 3 grms. (12 and 15 carats) by allowing a blowpipe flame, rich in hydrogen or carbon, to play on the extremity of a small cylinder of alumina, while a mixture of alumina and 2·5 per cent. of chromium oxide in the form of a powder is mechanically blown with the oxygen into the tube of the blowpipe, and thus deposited on the surface of the fused mass of alumina. The artificial stones thus obtained are identical in physical and crystallographical properties with the natural gems, from which, however, they can be detected by the presence of minute bubbles visible only under the microscope. A general view of the apparatus is illustrated in Fig. 49. The screw support, *S*, permits the moving of the molten mass into the proper zone of the flame, when it becomes necessary to increase the press. of the oxygen in the blowpipe, etc. The raw materials, contained in a wire-cloth basket placed in the chamber, *C*, are sifted by the slight impacts of the hammer, *B*, upon the anvil, *E*, which forms the top of the basket; and the powder, carried along in the central tube of the blowpipe, becomes distributed through the flame and undergoes fusion therein as soon as it reaches a support formed of a thin stick of alumina placed in the centre of the furnace, *F*. This powder, falling upon the alumina previously raised to a white heat, becomes agglomerated thereon, forming a cone, the point of which gradually rises until it reaches a zone of the flame hot enough to cause it to undergo fusion and form a filament. If, now, the press. of the oxygen be increased, this filament is converted at its apex into a sphere, the diameter of which it will gradually increase up to the extreme limits which with the heat of the blowpipe it is capable of reaching. *Les rubis reconstitués* have been discussed by H. Marour, I. H. Levin, E. Jannettaz, C. Doelter, I. Friedländer, H. von Löhr, H. Wild, R. Böttger, V. Merz, etc. A. Verneuil prepared sapphire blue crystals by a method similar to that employed for rubies, but with a mixture of alumina containing 1·5 per cent. of magnetic oxide of iron, and 0·5 per cent. of titanic oxide under reducing conditions in the oxy-hydrogen flame.

P. Hautefeuille synthesized corundum by the action of moist hydrogen fluoride on alumina at a red heat; and W. Bruhns heated alumina for 10 hrs. at 300° in a platinum tube with water containing a trace of ammonium fluoride, but at 250°, no crystallization occurred. C. Friedel obtained corundum and diaspore by heating amorphous alumina with a soda-lye at 450°-500°; at 530°-535°, only corundum was formed; and at 400°, only diaspore. J. Morris heated a mixture of alumina and carbon in a stream of carbon dioxide at a red heat. According to M. Houdard, by heating alumina with five times its weight of aluminium sulphide in the electric furnace, the crucible being suitably insulated to allow of slow cooling, a mass is obtained, which, on treatment with hydrochloric acid, leaves rhombohedral crystals of alumina. Attempts to produce coloured alumina crystals by means of chromium, under these conditions, were unsuccessful.

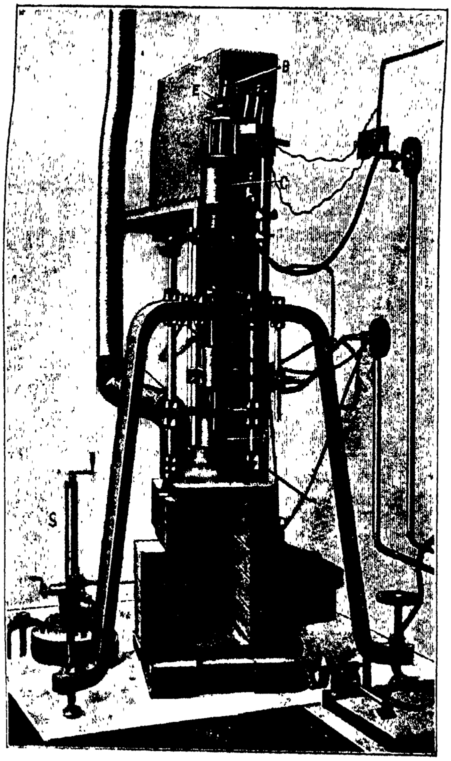

FIG. 49.—A. Verneuil's Apparatus for the Synthesis of Rubies.

(2) *The preparation of corundum by the crystallization of alumina from molten fluxes.*—M. A. Gaudin, as indicated above, heated alumina with potassium sulphate or sulphide; P. Hautefeuille and A. Perrey, alkali sulphide; L. Elsner, and R. Böttger, potassium dichromate; J. J. Ebelmen, borax (not boric acid); E. Frémy and C. Feil, lead oxide; F. Parmentier, potassium molybdate; S. Meunier, cryolite; J. Morozewicz, and A. Brun, a mixture of alkali or alkaline earth oxide and silica—*vide supra*; G. Medanich, potassium tungstate and calcium fluoride; P. Hautefeuille and A. Perrey, molten napheline and leucite (not artificial potassium nepheline). According to O. Hönigschmid, the product obtained on igniting a mixture of borax, aluminium turnings, and sulphur consists of crystalline alumina (artificial

corundum), with much amorphous boron and crystalline aluminium boride. H. A. Richmond and R. MacDonald melted the alumina with iron to remove silica. The slowly-cooled product was used as an abrasive.

(3) *The preparation of corundum by the decomposition of aluminosilicates.*—S. Meunier, and A. Lacroix obtained crystals of alumina by heating a mixture of cryolite and a silicate in a platinum crucible; F. Fouqué and A. Michel-Lévy, by heating fluorspar and microcline; and W. Vernadsky, by cooling molten potash mica.

(4) *The preparation of corundum by the decomposition of aluminium salts.*—According to C. Doelter, crystals of alumina are formed *auf nassem Wege* by heating aluminium salts with alkali carbonate. H. de Sénarmont, and C. R. C. Tichborne showed that when an aq. soln. of an aluminium salt is heated in a sealed tube at 350°, crystals of corundum are formed. E. Weinschenk prepared crystals of corundum, possibly accompanied by diaspore, by heating a soln. of aluminium sulphate with urea in a sealed tube at 180°–190°. A. Daubrée obtained crystals of corundum by the action of the vapour of aluminium fluoride on red-hot lime; H. St. C. Deville and H. Caron, by decomposing aluminium fluoride by boric oxide at a high temp.; H. Debray, by the action of an excess of alkali sulphate on red-hot aluminium phosphate—L. Grandeau found that if the temp. does not exceed 1400°, a complex alkali aluminium phosphate is formed; L. Schuch, by heating cryolite white hot in a current of steam; J. W. Mallet, by heating aluminium with sodium hydroxide in a carbon crucible; and S. Meunier, by heating aluminium chloride with magnesium or zinc and steam, or aluminium chloride and steam in a porcelain tube. According to P. Hautefeuille, alumina is not changed by heating it in a stream of hydrogen chloride, but aluminium salts furnish crystals of alumina—the oxalate or hydrocarbonate at a dull red heat, and the sulphate at a higher temp.—if chromic oxide be present, rubies are formed. H. Loyer prepared crystals of ruby by heating a mixture of alkali aluminate and chromic oxide in a stream of chlorine: $4NaAlO_2+2Cl_2=2Al_2O_3+4NaCl+O_2$.

V. Kohlschütter[10] and co-workers prepared alumina, dispersed in a gaseous medium, by making the metal the electrode of an electric arc, and oxidizing the vapour. The resulting fume was precipitated by a high tension electric field. R. Bradfield discussed the washing of colloidal alumina by the centrifuge.

§ 10. The Properties of Aluminium Oxide

According to G. A. Kenngott,[1] aluminium oxide has no taste or smell. The **colour** is white or water-clear ; the blue, red, yellow, brown, grey, or more rarely, violet or green colours of different varieties of corundum *e.g.* the sapphire, ruby, etc.--are due to the presence of pigmentary oxides. P. von Jeremejeff[2] found corundum crystals with blue and red ends, or with a yellow middle and blue ends. E. Frémy showed that chromium oxide is probably the colouring agent in rubies by synthesizing the gem-stone from alumina and chromic oxide ; he also suggested that chromium oxide is the colouring agent in the sapphire, but in a different state of oxidation from what it is in the ruby. J. W. Retgers inclined to the belief that the colouring agent is probably a small quantity of hydrocarbon, and not an inorganic constituent at all. L. Wöhler and K. von Kraatz-Koschlau could find no chromic oxide in rubies or in sapphires, but it must be remembered that an exceedingly small amount of the oxide has high tinctorial powers, and that quite a series of colours red, blue, yellow, and green can be obtained from chromium oxide ; it requires an oxidizing atm. to develop the red colour. The red colour of the ruby, heated under reducing conditions, may become green or appear colourless because of the low tinctorial powers of the green oxide. This explains the observations of C. Doelter, F. Rinne, and G. A. Kenngott, who noted that rubies sometimes became green or colourless when heated. C. Doelter found that some rubies could be heated white hot without change of colour. Whether or not the change occurs really depends on the nature of the atm. C. Doelter found that sapphires are decolorized at a white heat in air or oxygen, and he said that the colouring agent of sapphires is more likely to be organic than in the case of rubies. J. Morozewicz produced rose, yellow, greenish-yellow, red, or pale blue corundum by using iron oxide, and he considered the colouring agent is more likely to be iron oxide than chromic oxide. G. Forchhammer found that Siberian corundum contained 1·45 per cent. of ferric oxide and 0·34 per cent. of phosphoric oxide, and he considered the colouring agent to be iron phosphate. H. St. C. Deville and H. Caron obtained some blue patches in their experiments on the synthesis of rubies from alumina and chromic oxide, and they therefore inferred that the sapphire blue is produced by chromium in a lower state of oxidation than in rubies. In their experiments on bauxite, W. Gintl obtained blue patches of corundum which showed on analysis, TiO_2, 0·65 ; FeO, 0·79 ; MnO, 0·50 ; CaO, 1·85 ; MgO, 0·35 ; Na_2O, 2·07 ; SiO_2, 12·28 ; and Al_2O_3, 81·88. A. J. Moses found traces of ferric oxide and 0·1 per cent. of titanic oxide in artificial sapphires; and A. Verneuil found in sapphires from Australia, India, and Montana from 0·031 to 0·058 per cent. of titanic oxide and 0·56 to 0·92 per cent. of ferric oxide. A. Verneuil's syntheses of sapphires led him to believe that this coloration is produced by iron and titanium oxides. W. Hermann's observations on the action of reducing and oxidizing gases on heated corundum led him to infer that iron oxides act as tinctorial agents.

As indicated by C. F. Bucholz, and J. von Liebig, washed, precipitated alumina forms a light voluminous powder after ignition at a red heat. Fused alumina forms a white, hard, crystalline mass. The **crystals** of corundum belong to the trigonal system. According to G. Melczer, the axial ratios are $a : c = 1 : 1·3652$, and α 85° $43\frac{2}{3}'$; W. P. Davey gave 1 : 2726. Observations on the crystals have been made by H. de Sénarmont, A. des Cloizeaux, J. J. Ebelmen, L. Grandeau, O. Mügge, H. St. C. Deville and H. Caron, E. Frémy, A. Verneuil, J. H. Pratt, F. Rinne, etc. W. Crookes found that when snow-white alumina is exposed to the cathode rays, the amorphous powder acquires a pink colour, and is slowly crystallized.

There is a considerable variation in the form of the crystals of corundum from different localities; the prismatic, the flat, and the tabular forms are common; pyramidal crystals are not so common. The small crystals are usually well developed with smooth faces and edges; the larger crystals are often rough, striated, and tapering slightly towards the end like a barrel—hence the term *barrel corundum*. Penetration twins are not common. The most prominent twinning plane is parallel to the rhombohedron; and a repetition of the twinning may form a series of plates or laminæ in twin position. This gives a laminated or striated structure due to minute re-entrant and salient angles. W. E. Hidden observed crystals with a twinning plane parallel to the base. The fracture of corundum is irregular and conchoidal, and, as shown by J. L. Bournon, and J. W. Judd, certain specimens of corundum and sapphires exhibit no sign of cleavage. What was once thought to be cleavage was found by O. Mügge, M. Bauer, G. Tschermak, J. W. Judd, A. Lasaulx, to be a parting produced by mechanical or chemical forces, or possibly by both acting together. Corundum with the parting planes is inferior as an abrasive for cutting wheels, etc. The lustre of corundum is adamantine to vitreous; and that of emery is submetallic. The lustre on the basal plane of corundum is sometimes pearly. **Corrosion figures** in harmony with the trigonal system have been described by M. Bauer, R. Brauns, and G. Melczer.

According to G. A. Rankin and H. E. Merwin, alumina occurs in two distinct forms: α-alumina is the ordinary crystalline variety represented by corundum; and β-alumina, which is formed in small quantities in hexagonal crystals often in groups of overlapping triangular plates when pure alumina is melted and slowly cooled. The presence of magnesia (say, 0·5 per cent.) assists the transformation of α- to β-alumina, whereas the presence of lime or silica facilitates the formation of the α-variety. It has not been found possible to convert β-alumina to α-alumina by holding the former at temp. above or below the m.p., and it is therefore suspected that β-alumina is monotropic with respect to α-alumina.

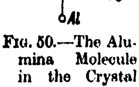

FIG. 50.—The Alumina Molecule in the Crystal Lattice.

F. Rinne, W. P. Davey and E. O. Hoffman, C. Mauguin, and J. A. Hedvall have studied the **X-radiograms** of alumina. The lattice is a rhombohedron with hexagonal axes 4·86 A., and a vertical axis 6·62 A. Thus, except for the difference in the axial ratio, the structure is identical with that of calcite. F. Rinne's illustration of the group Al_2O_3 as a chemical molecule in the crystal molecule is shown in Fig. 50. According to L. H. Milligan, the X-radiogram of alumina, prepared by the calcination of the crystalline hydroxide at 325°, gives no trace of the original hydroxide structure; and it is similar neither to diaspore which is the crystalline monohydrate $Al_2O_3.H_2O$, nor to corundum which is crystalline, anhydrous Al_2O_3. It does, however, show a distinct set of lines which are indicative of a crystalline condition. The absorption of water does not alter its structure, and none of the hydroxide is produced. Alumina, prepared by calcination at 600°, shows a faint pattern similar to the preceding sample, but the bulk of the material is probably amorphous. When calcination temp. somewhat above 1000° are employed, the product gives the pattern of corundum faintly and still higher ignition temp. increase the intensity of this pattern until it equals that of pure corundum. J. Beckenkamp also studied the space-lattice of corundum.

Reported values for the **specific gravity** of alumina vary from the 3·5311 of M. J. Brisson[3] and the 3·562 by P. van Muschenbroek to the 4·152 at 1° of A. le Royer and J. B. A. Dumas. A. H. Church gave 3·979 to 4·03 at 15·5°; L. Grandeau, 3·98 at 14°; and E. Madelung and R. Fuchs, 3·9804; F. G. Schaffgotsch gave 3·994 as a mean of nine determinations with the ruby; and L. F. Nilson and O. Pettersson, 3·990 for the sapphire. J. J. Ebelmen gave 3·928 for the sp. gr. of crystalline alumina. The best representative value for the sp. gr. of crystalline alumina is 3·99. The sp. gr. of the amorphous alumina increases with the temp. of calcination; thus J. W. Mellor and A. D. Holdcroft found that after heating precipitated alumina to

	600°	700°	800°	900°	1200°
Sp. gr. at 15°	2·82	2·83	3·39	3·53	3·92

H. Rose found the sp. gr. rose to 3·999 after ignition in a hard porcelain furnace, presumably about 1500°, and F. G. Schaffgotsch, to 4·008 after ignition. The sp. gr. of ignited alumina is therefore the same as that of corundum or crystalline alumina. C. J. St. C. Deville found the sp. gr. of crystals of corundum fell from 4·022 to 3·992 after melting in the blast gas flame. The hardness of corundum is exceeded by that of the diamond. F. Auerbach found the mineral to be rather harder in the direction of its principal axis than it is in other directions. A. Reis and L. Zimmermann, T. A. Jaggar, J. L. Smith, W. H. Emerson, and A. Rosiwal, have made observations on this subject. M. Bauer found that the hardness varies with different specimens; that of the sapphire is about 9 on Mohs' scale; and that of the ruby is 8·8 to 9·0. The hardness of emery is due to the contained corundum. The hardness is not the same as the abrasive efficiency; thus two examples of corundum may have the same hardness so far as power of scratching or being scratched by other substances is concerned, and yet have a different cutting or abrasive efficiency. E. Madelung and R. Fuchs gave for the **compressibility** coeff., $0·38\times10^{-6}$ megabar per sq. cm. According to F. Auerbach, the **modulus of elasticity** of corundum is very high, being 2·5 times that of steel, and exceeded only by that of iridium; the observed values are: Iridium 52,500, corundum 52,000, and steel 21,000 kgrms. per sq. mm.

According to H. Fizeau,[4] the coeff. of linear **thermal expansion** of blue Indian corundum is $\alpha=0·0_6619$ at 40° when taken parallel to the chief axis, and $0·0_6543$ when taken at right angles to that axis. Hence, the coeff. of cubical expansion is $0·0_41705$. F. Pfaff gives $0·0_66765$ for the coeff. of linear and $0·0_41995$ for the coeff. of cubical expansion taken between 0° and 100°. B. Bogitsch measured the thermal expansion of bauxite bricks. F. E. Neumann gave 0·1942 for the **specific heat** of corundum; H. V. Regnault, 0·19762 for the sp. ht. of corundum between 8° and 98°, and 0·21732 for that of sapphire between 7° and 97°; and J. Joly gave 0·1981 for the pale blue, prismatic crystals between 12·6° and 100°. L. F. Nilson and O. Pettersson gave 0·1827 for the sp. ht. of alumina, and 0·1879 for that of the sapphire. W. A. Tilden gave for the increase in the sp. ht. of alumina with rise of temp.,

	15°–100°	15°–195°	15°–315°	15°–420°	15°–510°
Sp. ht.	0·2003	0·2195	0·2311	0·2400	0·2460

According to H. von Wartenberg and G. Witzel, the **molecular heat** of alumina at 230° is 10·8 cals.; and at 1308°, 28 to 30 cals. E. Jannetaz gave 0·9 for the ratio of the **thermal conductivity** in the direction of the large and small axes. A. Weber gave 0·025 cal. per cm. per sec. per degree for the thermal conductivity of aluminium oxide.

L. B. G. de Morveau[5] fused alumina to a white enamel in a flame fed with oxygen; H. Davy fused it in the circuit of a voltaic battery; and F. Stromeyer, R. Hare, M. A. Gaudin, and E. D. Clarke, in the oxy-hydrogen blowpipe flame. The last-named said that molten ruby solidified to a white opaque globule, and that corundum and alumina each formed a yellow transparent glass. H. Moissan said that the **melting point** of alumina in a carbon crucible is 2250°, and added that the liquid crystallizes on cooling. C. W. Kanolt found that bauxite clay melted at 1795°; bauxite, 1820°; and purified alumina, 2010°; and later he gave 2050° for the m.p. of alumina. O. Ruff and co-workers gave 2010° ± 10° for the m.p. of alumina. E. F. Northrup melted the oxide in a crucible of titanic or zirconium oxide. E. Tiede and E. Birnbräuer found that in a vacuum furnace, alumina melts at 1890°, and volatilization begins at 1750°. O. Ruff gave 2040° as the best representative value for the m.p. of alumina containing 0·3 per cent. sodium oxide which volatilized early; 0·1 per cent. silica, and 0·05 per cent. of ferric oxide, and a trace of calcium oxide. For the **vapour pressure** in mm., O. Ruff and P. Schmidt found

	1830°	1840°	1930°	2018°	2070°	2125°
Vap. press.	7	11	108	230	300	750 mm.

According to H. Moissan, alumina can be completely volatilized at 2250°, and if the volatilization takes place in a carbon tube some aluminium metal and carbide are formed. W. R. Mott gave 3400° to 3700° for the **boiling point** of alumina, a number not consistent with O. Ruff and P. Schmidt's vap. press. curve.

J. J. Berzelius[6] showed that when a number of oxides—chromium, tantalum, rhodium, etc.—are heated to redness, some internal change occurs which is attended by the evolution of heat, and in some cases—*e.g.* zirconia—the mass becomes incandescent. H. le Chatelier found that the heating curve of alumina is dependent on the mode of preparation of the oxide. Thus, alumina precipitated from sodium aluminate furnishes a diminution corresponding with an endothermal change—decomposition of hydrates, etc.—below 360°, while alumina precipitated from an aluminium salt, and that prepared by the calcination of the nitrate show a hump in the curve corresponding with an exothermal reaction. These results were confirmed by J. W. Mellor and A. D. Holdcroft, H. S. Houldsworth and J. W. Cobb, etc.

If a thermocouple be placed in a mass of the uncalcined oxide in a crucible being heated in a furnace on a rapidly rising temp. so that the temp. is recorded every half-minute, a curve resembling that shown diagrammatically in Fig. 51 is obtained. The dotted line shows the course which would be followed by the curve if the oxide suffered no molecular change. The temp. of the oxide rushes beyond that of the crucible, and it then cools down until it coincides with the rising temp. of the crucible. The phenomenon can be called **calorescence**—*calor*, heat.

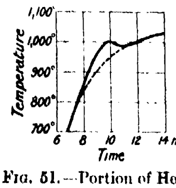

FIG. 51.—Portion of Heating Curve of Alumina showing Exothermal Change starting about 850°.

Before this change has occurred, alumina is very hygroscopic, but is not so after the calorescence is completed; the sp. gr. increases very much during the change; and the solubility in acids decreases in a marked degree. J. J. Berzelius found that gadolinite behaves similarly, and K. A. Hofmann and F. Zerban observed that the calorescence or glowing of this mineral occurs at a definite temp., *viz.* 430°. P. Scheerer observed a similar change with allanite, and he studied the action with gadolinite in some detail. He found that the vol. before and after calcination are as 1 : 0·943. He attributed this to an inter-molecular change involving a change in the relative positions of the molecules and a decrease of the inter-molecular distances. This he illustrates by assuming that the spherical molecules are openly packed before calcination, and closely packed after calcination. A. Damour observed a greater change—1 : 0·922—with Cingalese zircon than with gadolinite, and O. Hauser found risörite exhibited a still greater vol. change —1 : 0·90—and the mineral loses its water. Ammonium magnesium phosphate glows, loses ammonia, and is converted into magnesium pyrophosphate on calcination; and the mineral sipylite loses basic water, glows brilliantly, and forms, according to J. W. Mallet, pyrocolumbate. P. Scheerer's ingenious explanation is not of universal application, because H. Rose showed that samarskite exhibits the phenomenon of glowing but its sp. gr. is reduced so that there is an increase in vol. W. Ramsay and M. W. Travers found that fergusonite also decreases in sp. gr. from 5·62 to 5·37 when heated, and the mineral glows strongly at 500°–600°. H. V. Regnault assumed that the oxides observed by J. J. Berzelius should have a smaller sp. ht. after calcination than before, but he was not able to prove it, although H. Rose showed that the sp. ht. of gadolinite is reduced about one-fourteenth. With samarskite, H. Rose observed no difference in the sp. ht. and no glow effect on calcination. The nature of the molecular change which occurs on calcining these compounds has not been established. According to J. A. Hedvall, the X-radiograms of the different forms—artificial and natural—are the same, and the existence of different modifications has not been established. The evolution of heat, said H. le Chatelier, in the calcination of alumina is attended by a molecular change in the oxide. The thermal value of the change of alumina from the amorphous to the crystalline state was found by W. G. Mixter to be 10 Cals. M. Berthelot gave (2Al, 3O)=393·6 Cals. nearly for the **heat of formation** of alumina, and J. B. Baille and C. Fèry gave 380·2 Cals. According to J. W. Richards, the heat of formation is 387·20 Cals. at 0°, 421·408 Cals. at 900°, and 391·236 Cals. at 1100°, or, at $\theta°$, $(2\mathrm{Al}, 3\mathrm{O}) = 387{\cdot}20 + 192{\cdot}6\theta - 0{\cdot}1716\theta^2$ Cals. W. G. Mixter gave for amorphous alumina $\mathrm{Na_2O} + \mathrm{Al_2O_3} = 2\mathrm{NaAlO_2} + 40$ Cals.

The **double refraction** of corundum is feeble and negative, being from 0·008–0·009, that is, about the same as quartz. The **index of refraction** is high, being, on the average, 1·765. That of the diamond for the red Li-line is 2·4135; garnet (pyrope), 1·7776; sapphire, $\omega=1{\cdot}7678$, $\epsilon=1{\cdot}7598$; ruby, $\omega=1{\cdot}7675$, $\epsilon=1{\cdot}7592$; tourmaline, $\omega=1{\cdot}6347$, $\epsilon=1{\cdot}6172$; and emerald (beryl), $\omega=1{\cdot}5491$, $\epsilon=1{\cdot}5480$. Measurements were made by W. H. Wollaston,[7] D. Brewster, W. H. Miller, A. des Cloizeaux, and R. Brauns. G. Melczer found that the indices of refraction for natural crystals with the C-ray ranged from $\omega=1{\cdot}7643$–$1{\cdot}7687$, and $\epsilon=1{\cdot}7563$–$1{\cdot}7602$; with the D-ray, $\omega=1{\cdot}7675$–$1{\cdot}7715$, and $\epsilon=1{\cdot}7594$–$1{\cdot}7632$; and with the F-ray, $\omega=1{\cdot}7751$–$1{\cdot}7764$, and $\epsilon=1{\cdot}7668$–$1{\cdot}7682$. For artificial crystals with the C-line, $\omega=1{\cdot}7681$–$1{\cdot}7714$, and $\epsilon=1{\cdot}7597$–$1{\cdot}7628$; with the D-line, $\omega=1{\cdot}7715$–$1{\cdot}7745$, and $\epsilon=1{\cdot}7630$–$1{\cdot}7667$; and with the F-line, $\omega=1{\cdot}7789$–$1{\cdot}7818$, and $\epsilon=1{\cdot}7706$–$1{\cdot}7731$. The crystals are normally uniaxial, but some varieties are abnormally biaxial. The optical anomalies of crystals of corundum have been studied by A. des Cloizeaux, E. Mallard, E. Bertrand, G. Tschermak, A. Lasaulx, and R. Brauns.

The **pleochroism** in ordinary light is strongly marked in the deeper coloured varieties, especially rubies and sapphires. For example, the ruby may be deep coloured when viewed in the direction of the vertical axis, and a much lighter colour, or even colourless, when viewed at right angles to this direction; the sapphire may be deep blue in the direction of the vertical axis, and greenish-blue, greenish-white, or bluish-white when viewed at right angles. R. Brauns, J. W. Judd, O. Mügge, and F. Rinne have described the pleochroitic minerals. The pleochroism of the corundum gem-stones enables them to be distinguished from spinels and garnets. H. E. Ives and co-workers studied the emissivity and illuminating power of mantles made of alumina and heated by Bunsen's flame. V. Agafonoff measured the **absorption spectrum** of a rose-coloured Cingalese ruby and found an absorption band between the blue violet and the Cd-line. The absorption spectrum has also been investigated by F. Rinne, A. Miethe, and M. Chaumet. W. W. Coblentz found the **ultra-red emission spectrum** in the oxy-hydrogen flame has emission bands at $1{\cdot}4\mu$, 2μ, $3{\cdot}1\mu$, $4{\cdot}7\mu$, $5{\cdot}2\mu$, and $7{\cdot}5\mu$. The **reflecting power** for light of wave-length $\lambda=0{\cdot}60\mu$ is 84·1 per cent.; for $\lambda=0{\cdot}95\mu$, 87·7 per cent.; for $\lambda=4{\cdot}4\mu$, 20·8 per cent.; for $\lambda=8{\cdot}8\mu$, 1·99 per cent.; and for $\lambda=24\mu$, 6·5 per cent. F. Henning and W. Heuse also examined the ultra-red spectrum of the ruby. The transparency of corundum to the **X-rays** has been investigated by C. Doelter, who found it to be about one-tenth as transparent as the diamond, and he arranges some minerals in the order of their resistance to the passage of the X-rays: diamond, corundum, talc, quartz, rock-salt, etc. F. Bordas found that sapphires are discoloured by exposure to X-rays.

In 1820, P. Heinrich[8] stated that alumina exhibits a feeble **phosphorescence** when exposed to all kinds of stimuli. D. Hahn stated that Cingalese ruby exhibits a fine yellow **thermoluminescence**; the glow was very feeble with Cingalese and Brazilian sapphires; a grey corundum was found to give a bluish thermoluminescence at a low temp., and the glow became more intense as the temp. was raised, but it completely vanished after the mineral had been heated some time. Some samples of corundum and emery show no thermoluminescence. S. C. Lind and D. C. Bardwell observed no thermoluminesence with natural sapphire, and only a faint glow with artificial crystals. E. L. Nichols and H. L. Howes studied the luminescent spectrum of incandescent alumina. E. Newbery and H. Lupton said that a ruby from Carolina appeared green when strongly heated but regained its colour on cooling, the mineral showed a slight thermoluminescence which rapidly disappeared on further heating; they also found that exposure to **radium radiations** for 10 days had no appreciable effect on the colour, because the colouring matter is not exotic, for rubies are coloured intrinsically by chromic oxide; on the other hand, F. Bordas found that a sapphire exposed to radium bromide was coloured red, violet, blue, green, yellow, and brown. S. C. Lind and D. C. Bardwell found colourless crystals of sapphire generally become yellow; pink crystals become orange; and blue crystals become greyish or brownish-green; no fluorescence occurred. Light-coloured ruby was not changed, but synthetic ruby was slightly darkened; no fluorescence occurred. J. O. Perrine observed no ultra-violet fluorescence with alumina. C. Doelter studied the action of radium and ultra-violet radiations on sapphire. E. L. Nichols and D. T. Wilber noted that alumina exhibits **flame luminescence** in the zone of a hydrogen flame between reduction and oxidation. E. L. Nichols found that at 1000° in the oxy-hydrogen flame, alumina appears blue, not red. The brightness of the radiation at 1000° is 1900 times that of a black body at 665°, and twice as bright as that at 1500°. E. Becquerel showed that the phosphorescence of corundum increases in intensity as the amount of contained chromic oxide increases; and W. Crookes made a similar observation with respect to the phosphorescence under the influence of the **cathode rays**. According to H. Jackson, this kind of phosphorescence depends on the degree of exhaustion of the tube:

> At a high exhaustion, the alumina glowed with a splendid crimson light. As the exhaustion proceeded, a spot of about 3 mm. in diameter in the direct line of the centres of the electrodes glowed for a moment with increased brilliancy. This quickly died out, and for a short time the spot appeared black by contrast with the surrounding colour. Then came in rapid succession the various stages noticed on heating a substance up to a white heat. As the vacuum became higher, this bright light died out as it came, and once more the central spot looked black. Then when the vacuum was so high that the discharge nearly stopped in the tube, the phosphorescence of the central spot returned, and the glow was confined to this spot; but now the phosphorescence was blue.

L. de Boisbaudran said that purified alumina does not phosphoresce when exposed in vacuo to these rays, but if 15^{-5} part of chromic oxide be present, a distinct phosphorescence is produced, and with 10^{-3} part of chromic oxide, the effect is brilliant. It is inferred from the work of W. Crookes, L. de Boisbaudran, E. Becquerel, G. C. Schmidt, and W. Arnold that pure alumina does not phosphoresce. W. Weiff showed that alumina prepared by precipitation and dehydration of the hydroxide is not fluorescent or phosphorescent under the influence of the cathode rays, while that which is prepared by burning the powdered metal in air or oxygen is fluorescent and phosphorescent under the cathode rays, and also gives off oxygen under the influence of these rays. J. A. Wilkinson showed that the difference is not due to the formation of aluminium peroxide by the burning aluminium, but is rather due to the presence of sodium peroxide derived from the combustion of the sodium contained as an impurity in the metal. J. Rossignol, J. Ewles, and E. L. Nichols and D. T. Wilber studied the cathodo-luminescence of alumina. G. C. Schmidt found that alumina phosphoresces under the influence of the **canal rays** only when the alumina is impure; but J. Tafel takes the contrary view. J. A. Wilkinson's work shows that the difference in the reports is the result of inattention to the unsuspected impurities in the so-called pure alumina. According to F. Beijerinck, corundum is a non-conductor of electricity; and A. A. Somerville found powdered alumina to be one of the best of electrical insulators. For E. Thomson's **magneto-optical effect,** *vide* zinc oxide.

Alumina at a red heat is not affected by **hydrogen,** but H. N. Warren[9] obtained aluminium by reducing alumina with hydrogen while contained in a lime tube heated by the oxy-hydrogen blowpipe flame—*vide* aluminium. According to W. N. Hartley and co-workers:

> The actual energy supplied before alumina is reduced by carbon, carbon monoxide, or hydrogen is −82·5 Cals., −62·7 Cals., or −72·9 Cals., respectively. The carbon monoxide value is thus shown to be less than that in either of the other two reactions. Alumina is reduced to the metallic state in the oxy-hydrogen flame, and the reduction takes place more easily when the alumina is mixed with some dense form of carbon. In the first instance, the flame alone supplied hydrogen only as the reducing agent, consequently, the energy required for every atom of oxygen removed was 72·9 Cals. in the form of extraneous heat which was necessary not only for initiating the process, but also maintaining it. When solid carbon was used this was a somewhat higher figure, being 82·5 Cals., but this very reduction process with solid carbon would result in the formation of carbon monoxide which could then operate upon another mol. of alumina, which places the extreme limits of the energy required for reduction as between 63 Cals. and 82·5 Cals. From this it would appear that the reduction of alumina may be carried out in the oxy-hydrogen flame by a purely chemical action if the extraneous energy required to initiate and maintain the action does not exceed 82·5 Cals. per atom of oxygen removed.

According to J. Dewar, a gram of dry alumina at the temp. of liquid air adsorbs 70 c.c. of **air** at atm. press., but under reduced press. the adsorption rapidly decreases. M. Reichardt and E. Blumtrill found that aluminium hydroxide, air-dried and dried at 100°, absorbs from air, respectively, 11 and 69 c.c. of gas per 100 grms., and the gas contained respectively 41 and 83 per cent. of nitrogen; 0 and 19 per cent. of oxygen; and 59 and 0 per cent. of carbon dioxide. This remarkably selective absorption has potential applications. F. Scheermesser also noted that carbon dioxide is strongly adsorbed by alumina. C. F. Cross found that alumina dehydrated at a low red heat absorbs **water** corresponding with $Al(OH)_3$ when exposed to a moist atm., whereas alumina ignited over the gas flame rehydrates to $Al_2O(OH)_4$; and after blowpipe ignition, it rehydrates approximately to $AlO(OH)$—*vide* aluminium hydroxides. According to J. W. Mellor and A. D. Holdcroft, 100 grms. of alumina, which have been dehydrated at 800°, absorb 10·75 grms. of moisture, and that dehydrated at 1200°, 0·01 grm.; F. M. G. Johnson utilized this fact and found alumina dehydrated at a low temp. is a better drying agent for gases than calcium chloride, sulphuric acid, etc. H. Adkins discussed the use of alumina as a dehydration and decarboxylation agent; and S. Medsforth, the accelerating influence on nickel as a catalyst in the reduction of carbon monoxide or dioxide by hydrogen. For the **Pouillet effect** with alumina, *vide* 1. 9, 9.

H. Moissan found that, at ordinary temp., **fluorine** reacts with alumina, *toute la masse devient lumineuse,* forming the fluoride, and liberating oxygen; but **chlorine** has no apparent action on alumina at a red heat. These facts are taken to correspond with the heats of formation of the oxide, Al_2O_3, 380·2 Cals., of the chloride, $AlCl_3$, 161·4 Cals., and of the fluoride, AlF_3, 249·0 Cals. The heat of formation of the fluoride thus exceeds that of the chloride, and that of the oxide exceeds that of the fluoride. The reaction $2Al_2O_3+6Cl_2=4AlCl_3+3O_2-114·8$ Cals. being endothermal *does not occur. Aluminium chloride, however, is but incompletely decomposed by oxygen at a red heat*; and R. Weber found that at a white heat some aluminium chloride is formed by the action of chlorine on alumina. If alumina be mixed with carbon and heated in a stream of chlorine, aluminium chloride is formed by an exothermal reaction, $Al_2O_3+3Cl_2+3C=3CO+2AlCl_3+30·2$ Cals., the so-called *H. C. Oersted's reaction*, because the heat of formation of carbon monoxide, CO, 29·2 Cals., is capable of doing chemical work in the reaction. A. Duboin and A. Gautier showed that boron and silicon can take the place of carbon in H. C. Oersted's reaction, forming aluminium chloride, and in the one case boric oxide, and in the other case silica, but not silicon tetrachloride or silicochloroform. Similarly, the heated oxide is decomposed by carbon tetrachloride, as shown by E. Demarçay, and L. Meyer; the last-named obtained a similar result with chloronaphthalene; and H. N. Warren passed the mixed vapours of petroleum and chlorine over heated alumina and obtained aluminium chloride—*vide* aluminium chloride. If alumina be heated with an excess of **ammonium chloride,** part of the alumina is volatilized as chloride. L. Troost and P. Hautefeuille found that the vapour of **boron trichloride** also forms aluminium chloride and aluminium borate. According to A. Duboin and A. Gautier, **bromine** and **iodine** react on a mixture of boron and alumina in an analogous manner. A. Daubrée found the vapour of **phosphorus pentachloride** attacks heated corundum more slowly than amorphous alumina, forming phosphoryl chloride, and aluminium phosphate, and, according to R. Weber, a double compound of aluminium and phosphorus trichlorides. L. Troost and P. Hautefeuille found that **silicon fluoride** at a red heat reacts rapidly with alumina, forming, according to A. Daubrée, topaz. When **hydrogen chloride** is passed over a heated mixture of alumina and silicon, L. Troost and P. Hautefeuille found that aluminium chloride but no silicon chloride is formed. G. Gore found dry liquid hydrogen chloride converts alumina into the chloride without dissolving the product—*vide* aluminium chloride for the action of the gas. The solubility, or perhaps the rate of soln., of alumina in acids is greatly affected by the temp. at which the solid has been calcined. Like many others, H. le Chatelier found that if the temp. of calcination exceeds 850°, alumina becomes insoluble in acids. H. Rose said that calcined alumina dissolved slowly in boiling **hydrochloric acid.** J. W. Mellor and A. D. Holdcroft found that the amount dissolved by hydrochloric acid during 2 hrs.' shaking at 14°, from alumina calcined for 10 hrs. at

	600°	700°	800°	900°	1200°
Per cent. dissolved	42·96	20·40	7·84	5·92	0·00

O. Hönigschmid found that calcined alumina is indifferent towards acids, even a mixture of **hydrofluoric acid** and **nitric acid.** A. Mitscherlich said that corundum and crystallized alumina are insoluble in cold acids, but boiling **sulphuric acid** (8 : 3) attacks corundum slowly, and if the mixture be heated in a sealed tube, the dissolution is completed. A. Gautier found heated alumina is attacked by hydrogen sulphide, $4Al_2O_3+9H_2S=3SO_2+9H_2+2(Al_2O_3.Al_2S_3)$. E. Frémy found **carbon disulphide** at a red heat forms aluminium sulphide. The reduction of alumina by **carbon** is discussed in connection with aluminium, and the carbides. K. Nischk found that alumina in the presence of copper can be reduced by carbon, forming an alloy of copper with several per cent. of aluminium. L. Kahlenberg and W. J. Trantman found alumina is not reduced by **silicon.** The action of **calcium carbide, potassium,** and **magnesium** on alumina is discussed in connection with aluminium. E. Botolfsen showed that alumina is reduced by **calcium.** C. W. Scheele found alumina to be insoluble in **hydrocyanic acid.** O. Hönigschmid showed that calcined alumina is but slowly attacked by conc. soln. of **alkali hydroxide,** and by fused sodium hydroxide, or a mixture of fused **sodium**

carbonate and nitrate, but it is readily attacked by fused **potassium hydrosulphate.** E. J. Mills and C. W. Meanwell found that when fused with **sodium sulphate,** sulphur trioxide is evolved, and this the more the smaller the proportion of alumina. According to F. de Lalande and M. Prud'homme, a mixture of alumina and **sodium chloride** decomposes at a red heat in a stream of dry air or oxygen, and chlorine is evolved. G. Marchal found the reaction between **calcium sulphate** and alumina begins at 940°–950°. P. Ebell found that molten **glass** dissolves comparatively large quantities of alumina, and that most of this crystallizes out on cooling.

Bauxite has been used to a limited extent in making refractory bricks chiefly for rotary cement kilns, and for open-hearth basic steel furnaces where not only are fire-resisting qualities required but also a resistance to the corrosive action of slags. The bauxite is used alone, or admixed with a binding agent milk of lime or plastic fireclay. The bauxite may also be used to fortify ordinary fireclay. Bauxite bricks have an abnormally high shrinkage when in use unless they have been burned specially to a high temp. In order to lessen this shrinkage, the bauxite may be pre-calcined so as to convert it into corundum. A number of patents[10] have been obtained for the use of corundum or fused alumina in refractory goods. O. Ruff and W. Goebel[11] studied the preparation of plastic masses of alumina for making vessels of various kinds. The use of fused bauxite or corundum as a refractory has been discussed by A. Bigot, A. Granger, etc. One trade name for fused alumina is *alundum*. Other trade names have been given to the product- *corindite*, *diamantine*, *aloxite*, *oxyalumina*, *adamite*, *electrite*, etc. The by-product in the thermite reduction of chromic oxide is *corubin*. In the preparation of alundum, calcined bauxite is fused in a water-cooled arc-furnace. The impurities are to a certain extent reduced, and they partially segregate, as impure ferro-silicon, at the bottom of the fused mass. The fused alumina is crushed and mixed with the necessary proportion of a plastic clay and felspar to enable it to be moulded, and to impart the necessary binding power in the fired product. Numerous articles for the laboratory are made of alundum.

§ 11. Aluminium Hydroxides, and Peroxides

J. D. Dana,[1] and H. Lienau assume that there are three aluminium hydroxides, *viz.* *diaspore*, $Al_2O_3.H_2O$, *i.e.* $AlO(OH)$; *bauxite*, $Al_2O_3.2H_2O$, *i.e.* $Al_2O(OH)_4$; and *gibbsite* $Al_2O_3.3H_2O$, *i.e.* $Al(OH)_3$. The first and last are clearly defined hydroxides, but the individuality of bauxite is not so manifest, and the term is used generically for natural products with hydrated alumina as the dominant constituent. F. Cornu and K. A. Redlich, and B. Wohlin maintain that there are only the mono- and tri-hydroxides, and that bauxite is simply a mixture of the two. In support of this, B. Wohlin found that when bauxites of the mono-hydrate type are heated they showed a decided heat absorption at 540° while they were being dehydrated. Those of the trihydrate type showed a heat absorption at 310°, which was their dehydration temp. The minerals which had a composition corresponding to a dihydrate showed heat absorptions at both 310° and 540°.

The mineral **diaspore** was described by R. J. Haüy[2] at the beginning of the nineteenth century; it was analyzed by L. N. Vauquelin. R. J. Haüy named it diaspore after *διασπείρω*, to scatter, because, when introduced in a flame the mineral *se dissipe en une multitude de parcelles*. The source of R. J. Haüy's specimen was not known. G. Rose found a similar mineral during his travels in the Urals. Specimens from various localities have been analyzed by A. E. Nordenskiöld, C. H. Hess, A. Defrénoy, C. U. Shepard, A. Damour, R. Hermann, J. L. Smith, E. Hussak, C. T. Jackson, A. Löwe, M. Waterkamp, etc. The mineral may be regarded as **aluminium monohydroxide,** or as **meta-aluminic acid,** $HAlO_2$, whose salts—the meta-aluminates—are represented by the *spinels*. H. de Sénarmont,[3] E. Weinschenk, and G. Friedel obtained artificial diaspore accompanying corundum in the process they employed for synthesizing corundum (*q.v.*). A. C. Becquerel also separated soln. of potassium aluminate and chromic chloride by parchment paper and obtained a deposit of crystals of diaspore on the membrane—*vide supra*, laterite.

Diaspore occurs in nature in rhombic bipyramidal crystals with axial ratios, according to N. von Kokscharoff, $a:b:c=0{\cdot}93722:1,1:0{\cdot}60387$. According to K. Walther, aluminium monohydroxide is dimorphous, for he obtained a mineral from Cerro Redondo, Minas, Uruguay, which he named kayserite—after E. Kayser. Its composition was $AlO(OH)$, and the monoclinic crystals had a micaceous cleavage. The fracture of diaspore is conchoidal. The crystals are isomorphous with göthite, $Fe_2O_3.H_2O$, or $HFeO_2$, and with manganite, $Mn_2O_3.H_2O$, or $HMnO_2$. The crystals are colourless, but if contaminated with ferric oxide they may be tinted cream, grey, or brown; violet crystals have also been reported. The pleochroism of the coloured crystals has been described by W. Haidinger, appearing violet-blue in one direction, reddish plum-blue in another, and pale asparagus-green in a third direction. Diaspore may occur in foliated masses, in thin plates, or it may be stalactitic. The sp. gr. ranges from 3·3–3·5; and the hardness, 6–7. K. Walther gave 5–6 for the hardness of kayserite. G. Spezia fused diaspore to a colourless glass, by heating it in the flame of a blowpipe fed with oxygen. According to A. Mitscherlich, the mineral loses no water at 100°, but water is given off at a red heat. According to A. des Cloizeaux, the double refraction is strong and positive; and A. Michel-Lévy and A. Lacroix give for the indices of refraction in Na-light, $\alpha=1{\cdot}702$, $\beta=1{\cdot}722$, $\gamma=1{\cdot}750$. K. Walther gave for the indices of refraction of kayserite, $\alpha=1{\cdot}68$, and γ below 1·74; and the birefringence was 0·055. A. Kenngott said that when powdered and calcined diaspore is moistened with water, it has an alkaline reaction. According to A. Damour, diaspore is not attacked by acids or potash-lye; but after calcination it is soluble in sulphuric acid. According to F. Beijerinck, diaspore is a non-conductor of electricity.

H. Davy[4] analyzed a mineral found by W. Wavel at Barnstaple (Devonshire) and reported it to contain approximately 70 per cent. alumina and 30 per cent. water with about 1·4 of calcium oxide and some fluorine. He said that B. G. Babington proposed to call the mineral *wavellite*, but "if a name founded on its chemical properties be preferred, it may be denominated *hydrargillite*, from ὕδωρ, water; ἄργιλλος, clay." J. J. Berzelius, and J. N. von Fuchs, however, showed that what H. Davy assumed to be alumina was really aluminium phosphate. The term wavellite now refers to the aluminium phosphate, and hydrargillite to the hydrated alumina, but for a time, as a result of H. Davy's mistake, the two minerals were confused. T. Thomson called the Devonshire mineral *devonite*, and J. N. von Fuchs, *lasionite*. C. Dewey found a mineral at Richmond (Mass.) containing water and alumina, and called it **gibbsite** in honour of G. Gibbs. Analyses made by J. Torrey, B. Silliman, and J. L. Smith and G. J. Brush corresponded with $Al(OH)_3$; G. Rose applied H. Davy's name **hydrargillite** to a similar hydrate found in the Urals; and analyses by R. Hermann, F. von Kobell, K. von Hauer,

J. H. Gladstone, A. von Liebrich, F. Kovar, L. L. Fermor, A. E. Nordenskjöld, H. Warth, A. Mitscherlich, H. Gorceix, A. de Schulten, J. da Costa Sena, E. Jannettaz, and W. C. Eustis of other specimens agree with C. Dewey's gibbsite. G. J. Brush, and G. A. Kenngott discussed the more appropriate term gibbsite or hydrargillite for the mineral. Crystallized gibbsite or hydrargillite is comparatively rare. According to A. de Schulten,[5] the crystals of trihydrated alumina obtained by many processes are of artificial gibbsite, or hydrargillite, or **aluminium trihydroxide,** $Al_2O_3.3H_2O$, or $Al(OH)_3$—*e.g.* it is formed when a sat. soln. of aluminium hydroxide in dil. ammonia is warmed on a water-bath so that the ammonia is but slowly expelled; or when a slow current of carbon dioxide is passed over the surface of a warm alkaline soln. of alumina. J. M. van Bemmelen also showed that the aluminium hydroxide precipitated by L. le Chatelier's process (*vide supra*) by passing carbon dioxide through a boiling soln. of alkali aluminate; or by C. J. Bayer's process, by the action of aluminium hydroxide on a soln. of alkali aluminate (*vide supra*) is crystalline trihydroxide. M. Buchner treated the aluminium salt in the solid state with alkali soln., or the salt was moistened with a very little water and subjected to the action of gaseous ammonia. The salt was also dissolved in its water of crystallization and treated with ammonia, or a metallic oxide or hydroxide, with or without steam. Crystals of this hydroxide were also made by P. A. von Bonsdorff, as previously indicated; F. Wöhler obtained the crystals by boiling a piece of aluminium in water for many hours; C. Weltzien, by the action of hydrogen peroxide on aluminium; and A. Cossa, by the action of water on aluminium amalgam. A. C. Becquerel obtained crystals of the same product by separating soln. of potassium aluminate and aluminium chloride by a diaphragm. T. Schlösing obtained the same trihydrated alumina by calcining the enneahydrated nitrate at 140°; and M. Dullo obtained this hydrate in the form of a white powder by the electrolysis of an aq. soln. of alum.

Some colloidal forms have been reported. Thus, T. A. Nicolaewsky applied the term *shanyawskite* or *schanyawskite* after A. L. Shanyawskite or A. L. Schanyawskite—to an amorphous hydrated alumina, approximating $Al_2O_3.4H_2O$, which he found in crevices in the dolomite near Moscow. O. Pauls suggested that bauxite contains a large proportion of a colloid which he called *alumogel;* M. Kispatic, and F. Tucan called the colloidal alumina in bauxite corresponding to diaspore, $Al_2O_3.H_2O$, *sporogelite*, and F. Cornu called it *a-kliachite*, while that corresponding to hydrargillite, $Al_2O_3.3H_2O$, was called *a-kliachite*. The kliachite is also called *chachite* or *kljakite*—after Khache in Dalmatia. *Vide* bauxites.

The artificial crystals of gibbsite are white, the natural crystals may be grey, greenish-grey, brown, or yellow. W. Haidinger showed that the coloured crystals may be pleochroic. Crystals of gibbsite are not common; the mineral is usually stalactitic, or it may occur in small mammillary masses with a faint fibrous structure. N. von Kokscharoff supposed the mineral to be trigonal, but A. des Cloizeaux, and W. C. Brögger showed that the crystals are monoclinic prisms, with axial ratios $a:b:c=1\cdot70890:1:1\cdot91843$, and $\beta=85^\circ\ 29\frac{1}{8}'$. P. Groth suggested that gibbsite, $Al(OH)_3$, and boric acid, $B(OH)_3$, are isomorphous. O. Mügge described the basal cleavage; and W. C. Brögger, the twinning. According to L. H. Milligan, X-radiograms of crystalline aluminium hydroxide, prepared by Bayer's process, resemble those of the mineral gibbsite, thus showing it to be a definite crystalline compound. The sp. gr. ranges from 2·3–2·4—A. de Schulten gave 2·423; the hardness is between 2 and 3. According to J. M. van Bemmelen, at 170°, the composition remains $Al_2O_3.3H_2O$, *i.e.* $Al(OH)_3$, but after 20 hrs.' heating to 200°, the composition approximates $Al_2O_3.2H_2O$; if heated for a long time at 225°, $Al_2O_3.H_2O$ is formed, and this change is completed at 300°; and if heated to 320°, still more water is given off. W. Ramsay, T. Carnelley and J. Walker, and E. Martin investigated the dehydration of aluminium hydroxide—*vide infra*. L. H. Milligan showed that crystalline aluminium hydroxide remains constant in composition, $Al(OH)_3$, up to 145°. The evolution of water commences just over 145°, and is almost complete at 200°; about 8 per cent. of the original aluminium hydroxide remains undecomposed at this temp. There is no evidence of the formation of other hydrates. The water absorbed by alumina dehydrated as low as 275°, is simply adsorbed, and does not combine chemically with the alumina. T. Hagiwara found that aluminium hydroxide lost only 0·18 mol of water at 180°, but if previously ground with four times its weight of quartz, it lost 2·01 mols. This is taken to mean that the affinity of a substance for water is lessened by subdivision, since the chemically combined water becomes adsorbed water.

H. Rose, and C. F. Cross found that dehydrated alumina recombines with water with the evolution of heat, and this the less the higher the temp. at which the alumina has been heated—*vide* aluminium oxide. A. Mitscherlich found that the hydroxide dehydrated at about 240° reforms the trihydrate in moist air. J. Thomsen gives for the heat of formation (2Al, 3O, $3H_2O$), 388·80 Cals.; and (Al, 3O, 3H), 296·94 Cals. The double refraction is strong and positive. W. C. Brögger gave for the indices of refraction $\alpha=\beta=1·5347$, and $\gamma=1·5577$; and F. Slavik gave 1·560–1·573. W. W. Coblentz found a wide band at 3μ in the ultra-red transmission spectrum of bauxite, and other bands at $4·7\mu$, $5·8\mu$, and 7μ. In the ultra-red transmission spectrum of hydrargillite, W. W. Coblentz found one large water-band at 3μ; and in that of diaspore a band at 3μ, and smaller bands at $1·9\mu$, $5·8\mu$, and $6·7\mu$. In the ultra-red reflection spectrum, there are no marked absorption bands up to 8μ; there is a broad band between $9·4\mu$ and $10·3\mu$ with maxima at $9·45\mu$, $9·8\mu$, and $10·2\mu$. The region 12μ to 13μ is complex, but there is a maximum at $12·8\mu$. There are also maxima at $8·55\mu$, $13·8\mu$, and $14·6\mu$. F. Beijerinck said that gibbsite is a non-conductor of electricity. F. Wöhler, P. A. von Bonsdorff, A. Cossa, and V. Zunino noted the relative chemical inertness of crystallized aluminium trihydroxide. The crystalline trihydroxide is said to be insoluble in water, aq. ammonia, alcohol, and to be almost insoluble in cold sulphuric, hydrochloric, or nitric acid, and alkali-lye; to be very slowly soluble in boiling hydrochloric acid; and rapidly soluble in hot sulphuric acid. J. M. van Bemmelen found that the crystalline hydrate has not the power of adsorbing salts from soln. to any marked degree.

Hydrated alumina not only occurs crystalline in the form of definite hydroxides, but it may be obtained in a non-crystalline or amorphous state, as exemplified by the colloidal **alumina hydrogel** which is very sparingly soluble in water, and the so-called soluble hydrate in the form of an **alumina hydrosol.** The formation of alumina hydrogel by adding ammonia, or alkali hydroxides, has been described in connection with the formation of aluminium oxide. E. J. Mills and R. L. Barr[6] found that by adding sodium carbonate to a soln. of alum, the mixture remains clear until the molar ratio $Na_2CO_3 : Al_2(SO_4)_3$ is 3 : 5; when the ratio is 7·5 : 5 half the alumina is precipitated as hydroxide, and when the ratio is 12 : 5, all the alumina is precipitated. The amount precipitated in the first half of the reaction is proportional to the amount of sodium carbonate, and after that an increasing amount is precipitated. According to C. Renz, when a soln. of aluminium nitrate is precipitated by an excess of ammonia, a small quantity of aluminium hydroxide remains dissolved, but freshly precipitated and washed alumina is quite insoluble in ammonia. When a soln. of potassium aluminate is precipitated by the calculated quantity of ammonium chloride and a large excess of ammonium hydroxide is rapidly added, the precipitate completely redissolves. The modification of aluminium hydroxide soluble in ammonia is best prepared by addition of the calculated quantity of ammonium sulphate to a soln. of barium aluminate to which an excess of ammonia has been added. On filtering off the barium sulphate, a clear soln. is obtained, containing 0·1 grm. of alumina in 50 c.c., and on evaporation, it leaves the hydroxide as a white, not horny mass, dissolving less readily in acids than the ordinary modification. The filtration and washing of the hydrogel causes it to lose its property of dissolving in ammonia so that it appears as if there are two varieties of the hydrogel, one soluble and the other insoluble in aq. ammonia. The product was investigated by E. Wendehorst, G. Jander and B. Weber, L. Blum, R. Fittig, F. Tucan,

P. P. von Weimarn, etc. According to G. Lösekann, hydrogen sulphide precipitates hydrated alumina from alkaline soln., and the precipitate dissolves when the mixture is boiled—presumably by a reversal of the reaction. E. Schlumberger found that when the precipitated hydroxide is washed to remove the alkali salts, it loses to a large extent its solubility in acids. The product is assumed to be a mixture of soluble and insoluble colloids which may be separated by dil. hydrochloric acid, or alkali-lye. He said that the composition of the precipitated hydrates is not very definite, and he claimed to have made $Al_{10}O_{22}H_{14}$, *i.e.* $10Al(OH)_3$ less $8H_2O$, or $5Al_2O_3.7H_2O$; and $Al_6O_{14}H_{10}$, *i.e.* $6Al(OH)_3$ less $4H_2O$, or $3Al_2O_3.5H_2O$. The latter hydrate is represented by the formula:

$$Al_2(OH)_4{<}\genfrac{}{}{0pt}{}{O}{O}{>}\underset{HO\wedge OH}{Al_2}{<}\genfrac{}{}{0pt}{}{O}{O}{>}Al_2(OH)_4$$

but a formula cannot materialize a *compound*. It is said to be very hygroscopic, to swell up in cold conc. sulphuric acid, but not to dissolve unless the acid is heated, when it forms normal aluminium salts; on the other hand, it dissolves with great ease in cold, dil. hydrochloric acid to a viscous, opalescent, but homogeneous liquid, which passes through filter-paper. This liquid, which is acid and astringent, appears to coagulate when conc., and the dried coagulum forms a gummy mass of the composition, $Al_6O_{14}H_{10}.HCl$. When the soln. of the *hydrochloride* is dialyzed, normal aluminium chloride is eliminated, and the original basic hydroxide remains. W. Pauli regarded the colloidal particles as complexes like $Al(OH)_3.Al(OH)_2Cl$, etc.—*vide* oxychlorides. According to R. Willstätter and H. Kraut, aluminium hydroxide is prepared (i) as a pale yellow, plastic mass by precipitating aluminium sulphate with conc. ammonia and subsequent protracted heating of the precipitate with ammonia; (ii) as a very pale yellow, viscous, plastic mass prepared in the same manner as (i), but with avoidance of protracted heating; (iii) as a pure white, very voluminous, and very finely divided substance, by precipitating aluminium sulphate with dil. ammonia without protracted heating; and (iv) as a pure white, coarse powder by passing a slow current of carbon dioxide through a soln. of potassium aluminate. The chemical behaviour of the products towards a one per cent. soln. of sodium hydroxide, warm 12 per cent. acetic acid, or 1, 15, or 30 per cent. hydrochloric acid, differs in the several cases, and cannot be explained on purely chemical or purely colloid-chemical grounds. The existence of definite hydrates in the preparations is indicated by the results of their desiccation over sulphuric acid and by their step-wise dehydration at gradually increasing temp. The adsorptive capacity of the different varieties for the enzymes invertase and lipase is affected to a very marked extent by the dilution of the soln. V. Kohlschütter and co-workers investigated the dependence of the properties of dispersed aluminium hydroxide on the mode of preparation.

D. Tommasi found that the hydrate precipitated by ammonia, has the composition $Al(OH)_3$ after it has stood under water for 3 months—probably the product is here the crystalline hydrate, because its solubility in hydrochloric, nitric, or acetic acid or in alkali-lye is said to be as difficult as that of the calcined oxide, although it is easily soluble in conc. sulphuric acid. L. Péan de St. Gilles found that after boiling precipitated alumina with water for 20 hrs. the composition approximates $Al_2O_3.2H_2O$; but if heated with water to 260°–300°, in a sealed tube, A. Mitscherlich found 17·78–18·00 per cent. of water was retained. J. Löwe found that the hydrate precipitated by ammonium chloride from alkaline soln., and dried at 100°, is nearly $Al_2O_3.2H_2O$. E. T. Allen is of the opinion that precipitated alumina has the composition $Al(OH)_3$, whether prepared by precipitating warm or in the cold with ammonia, by boiling a soluble aluminate with ammonium chloride, by boiling the basic carbonate with water or dil. ammonia, or by the prolonged action of water on soluble aluminates. The last form is crystalline and does not lose water over sulphuric acid; the amorphous varieties under such conditions, or by heating at 110°, lose a mol. of water, leaving the hydrate, $Al_2O_5H_4$, which is hygroscopic and reverts to $Al(OH)_3$.

Alumina hydrogel dries to a white, hard, horny mass which, like dried glue, sticks to the tongue, and with water it forms a sticky mass. Alumina precipitated in the cold from not too dil., colloid-free soln. was found by F. Haber to be amorphous when tested by the X-radiogram method. Alumina prepared by peptizing the acetate *vide infra* and filtering through a colloid filter, left a membrane of alumina which gave evidence of a crystalline structure. S. Hakomori studied the failure of ammonia to precipitate aluminium hydroxide in the presence of tartaric acid or glycerol, but without coming to very definite conclusions. J. Löwe said that the alumina precipitated from alkaline soln. by ammonium chloride is more opaque than that precipitated by ammonia. J. J. Berzelius found that the precipitate dried at 110° was eq. to $Al(OH)_3$. E. T. Allen said that the hydrate has the greatest sp. gr. when precipitated from basic carbonate soln., but the sp. gr. of the crystalline hydrate is greater than that of the most dense hydrogel. A. Mitscherlich noted that the dried precipitate loses a little water at 130°, and the greater part is expelled between 150° and 280°, so that at the latter temp. the residue has the composition $Al_2O_3.H_2O$; the remaining water is retained until the temp. is bright red. The Compagnie des Produits Chimiques found the precipitate is readily dehydrated if the calcined mass is moistened with hydrofluoric acid and recalcined, although the final product then contains about one per cent. of fluoride. W. Ramsay, and T. Carnelley and J. Walker measured the rate at which water is given off at different temp., but found no signs of a discontinuity corresponding with the formation of definite hydrates. J. M. van Bemmelen also showed that, when heated, alumina hydrogel is constantly changing molecularly, so that at no period can it be represented as a chemical individual with a simple formula. W. Ramsay found that the hydrate, heated at 100°, has 29·5 per cent. of water; at 145°, 23·5 per cent.; at 200°, 19·8 per cent.; and at 300°, 15 per cent. W. Müller-Erzbach made some observations on this subject.

The attempts to fix a definite formula for alumina hydrogel have not been successful. J. M. van Bemmelen precipitated it by ammonia, and found that the colloid obtained (i) with very dil. soln of aluminium chloride and ammonia, when rapidly washed and dried in air, had the composition $Al_2O_3.4{\cdot}3H_2O$; but if obtained (ii) from conc. soln., $Al_2O_3.4{\cdot}45H_2O$; if the latter be boiled with water 24 hrs., (iii), or allowed to stand under water 6 mons., (iv), and then dried in air, the composition is $Al_2O_3.4{\cdot}4H_2O$. In spite of the similarity in composition, the four substances behave differently when allowed to stand in air sat. with water vapour, or when dried at 100°, or over conc. sulphuric acid. The water lost at 140° and 300° is different; but in all cases, when dried between 250° and 300°, the composition approximates $Al_2O_3.H_2O$. When (iii) has been heated to 100°, its composition corresponds with $Al_2O_3.3H_2O$; but (ii) has 1·85 mols of water after standing at 100° for one hour, and 1·4 mols of water after standing at 100° for six hours or more, while if it has stood an hour over conc. sulphuric acid, it contains 1·99 mols of water, and after 9 days, 1·6 mols of water. In general, the more water the colloid has lost by heat, or the longer it has stood under water, the more difficultly soluble it is in nitric or hydrochloric acid. The power of readsorbing water also decreases as the period of drying is extended. For instance, (i) and (ii) when dried at 100° until they have respectively the compositions $Al_2O_3.2{\cdot}3H_2O$ and $Al_2O_3.1{\cdot}8H_2O$, can absorb the original quantity of water from a moist atm.; but if dried over sulphuric acid, the former can take up 1·4 mols of water and the latter 1·8 mols. If (i) is heated to 300° until its composition is $Al_2O_3.0{\cdot}9H_2O$, it forms $Al_2O_3.3{\cdot}3H_2O$ in a moist atm.

According to J. M. van Bemmelen, alumina hydrogels, whether freshly precipitated or dried, adsorb acids, bases, and salts from soln. W. Pauli considers that complexes $Al(OH)_3.Al(OH)_2Cl$, etc., are formed. H. von Zehmen studied the reversible hydration and dehydration of the colloidal alumina prepared by H. Wislicenus. On heating, the loss of water takes place stepwise between 100° and 200°, inasmuch as a definite percentage of water is lost at any given temp.; 6·5 per cent. is lost at 100°, a further 3 per cent. at 150°, and 2–3 per cent. at 200°;

and above 200°, there is no further loss. On keeping in an open dish, practically the whole of the water is readsorbed in one day, and the small residue in four to five days. The maximum absorption of water is 60 per cent., and this amount is taken up in a few weeks by keeping the fibrous material in an atm. sat. with water vapour. In taking up water, swelling occurs; thus 1·97 grms. of material dried at 200°, had a volume of 5·60 c.c., and on keeping for three days in an atm. sat. with water vapour, it increased in weight to 3·12 grms. and in volume to 6·30 c.c. According to A. Tian, the hydrosols of the metal hydroxides are usually not very stable; it is exceptional for the hydrosol produced by the hydrolysis of the metal salt to flocculate. This is because the tendency of the particles of the hydrosol to unite to form particles of greater size is reversible owing to the chemical forces tending to peptization, and an equilibrium is established. The adsorption of salts, etc., by alumina hydrogel was studied by R. Warington, D. Strömholm, H. Rheinboldt and E. Wedekind, H. von Euler and R. Nilsson, H. B. Weiser and E. B. Middleton, S. Wosnessensky, etc. It is impossible to precipitate hydrated alumina from soln. containing other salts, without adsorption phenomena. This explains the trouble the early chemists had in precipitating alumina from alum soln. The product always contained adsorbed sulphates, and this is the origin of the statement that the precipitate is contaminated by a basic sulphate. N. R. Dhar and K. C. Sen found that when aluminium hydroxide gel is peptized by alkali hydroxides, it is negatively charged owing to the adsorption of hydroxyl ions. The adsorptive power of alumina for sucrose, leucine, phosphates, and nucleic acids has been studied by H. von Euler and E. Erikson. A. Charriou showed that if precipitated aluminium hydroxide containing adsorbed chromic acid be washed with a 5 per cent. soln. of a salt of a monobasic acid (chloride, bromide, iodide, nitrate, or acetate), no chromic acid is removed and no further substance adsorbed. With soln. of salts of a polybasic acid (carbonate, sulphate, sulphide, oxalate, tartrate, citrate, phosphate, or arsenate), interchange occurs between adsorbed chromic acid and polybasic acid. Sulphuric acid adsorbed by aluminium hydroxide is not displaced by monobasic acids, but completely so by polybasic acids. Phosphoric acid adsorbed by aluminium hydroxide is not displaced by carbonate or chromate soln. Carbonic and chromic acids are mutually displaceable from adsorption in aluminium hydroxide, that acid being displaced which is present in smaller concentration. When arsenious sulphide is precipitated by means of hydrogen sulphide in presence of a barium salt, the precipitate contains adsorbed barium. When the precipitate is washed with a soln. of sodium or potassium chloride, no displacement of barium occurs, whilst with soln. of aluminium, ferric and chromic chlorides, an interchange of barium and the tervalent metal takes place. A. Ivanitzkaja and L. Orlova studied the coagulation of alumina sols by electrolytes. M. A. Rakuzin found aluminium hydroxide adsorbs gum arabic from its aq. soln. irreversibly; while potassium metasilicate and sodium fluosilicate are adsorbed reversibly. H. von Euler and E. Erikson showed that sucrose and leucine are not adsorbed, while nucleic acid is adsorbed. They also studied the adsorption of phosphoric acid. According to H. Heidenhain, aluminium hydroxide, in the presence of a large excess of alkali tartrate, is neutral in the cold towards phenolphthalein, and, consequently, under these conditions acids can be titrated in the presence of acids. F. Mylius and F. Förster state that alumina hydrogel reacts like an acid towards iodeosin. W. H. van de Sande Bakhuyzen found that the solubility of the amphoteric oxide passes through a minimum when increasing quantities of acid and base are added. V. Kohlschütter and co-workers found that sol formation precedes the dissolution of aluminium hydroxide in conc. hydrochloric acid, but not in soda-lye; with aluminium oxide, sol formation precedes dissolution in both acids and bases. A. Massink has studied this subject. R. Schwarz and H. Stock found aluminium hydroxide acts as a negative catalyst on the photochemical decomposition of silver bromide emulsions.

R. Phillips noted that alumina hydrogel, freshly precipitated and washed in the cold, is readily soluble in acids, but if kept under water for some days, it becomes sparingly soluble; and L. Péan de St. Gilles, D. Tommasi, J. M. van Bemmelen, and many others have noted this ageing of alumina hydrogel by keeping under water, or by boiling with water, whereby the product becomes sparingly soluble in acids or alkali-lye. By means of X-radiograms, J. Böhm and H. Niclassen noted the passage from the amorphous to the crystalline state during the ageing of the gel. Like aluminium oxide, the hydroxide is converted into a product soluble in water, by fusion with the hydroxides of the alkalies or alkaline earths; with alkali hydrosulphate or pyrosulphate; or, according to H. C. McNeil, in fused barium chloride. P. N. Raikow said that alumina is not affected by carbon dioxide, and F. Sestini found that 100 c.c. of water, sat. with this gas at ordinary press., dissolve 0·001 grm. of alumina. T. Curtius and J. Rissom noted that hydrated alumina is not soluble in aq. hydrazoic acid. According to a patent of Hermania, the hydrolysis of soln. of basic aluminium salts is retarded if 0·1 per cent. of phosphoric acid or soluble phosphate be present.

C. Renz prepared a form of hydrated alumina soluble in ammonia—*vide supra.* The reports as to the solubility of precipitated alumina in ammonia are conflicting. C. Renz, and F. J. Malaguti and J. Durocher discussed the solubility of alumina in aq. ammonia. Alumina hydrogel is flocculated by salt soln., and deflocculated or peptized when these salts are removed by washing. H. B. Weiser and E. B. Middleton studied the conc. of different salts required to precipitate colloidal alumina—the order, beginning with the lowest, is ferrocyanide, thiosulphate, ferricyanide, citrate, sulphate, oxalate, phosphate, chromate, dithionate, dichromate, chloride, nitrate, bromide, and iodide. The adsorption of the salts by the precipitated colloid was also measured. N. Schilow studied the adsorption of soln. of electrolytes by alumina. Peptized alumina hydrogel will pass through filter-paper, and in some respects behave as if it were in soln. Hence, no doubt, some mal-inferences have been made as to the solubility of alumina. P. Klein found colloidal alumina is not precipitated by a number of non-conducting organic liquids. If ammonium salts are present, as is usually the case in analytical work, boiling the precipitate with the ammoniacal mother liquid may decompose the ammonium salts, resulting in the escape of ammonia and the production of free acid which dissolves the alumina. If fluorides be present, F. P. Veitch, W. R. Bloor, L. J. Curtman, and F. W. Hinrichsen showed that some alumina may escape precipitation; and J. W. Mellor showed that this is also the case if sulphates be present. The solubility of aluminium hydroxide in soln. of aluminium sulphate has been measured by R. Kremann and K. Hüttinger.

E. H. Archibald and Y. Habasian found that at 20°, the ammonia solubility of aluminium hydroxide, expressed in grams of aluminium hydroxide, $Al(OH)_3$, per 100 c.c., increases as the conc. of the ammonium hydroxide increases, until a conc. of about $0{\cdot}5N$-NH_4OH is attained when the solubility decreases as the conc. of the ammonia increases; thus,

N-NH_4OH* . .	0·050	0·100	0·125	0·200	0·500	1·000
Solubility $Al(OH)_3$.	0·007	0·008	0·025	0·038	0·045	0·024

In the presence of ammonium nitrate, the solubility decreases, and in the presence of potassium nitrate the solubility increases. Thus, with N-soln. of ammonia at 20° containing the salts just indicated in amounts represented as per cent. by weight:

	NH_4NO_3				KNO_3	
Salt . . .	5	10	20	30	5	10
Solubility $Al(HO)_3$.	0·0187	0·0082	0·0045	0·0035	0·0760	0·1310

L. de Boisbaudran found that if ammonium salts be present hydrated alumina is dissolved by aq. ammonia; J. Hanamann found a litre of 4 per cent. aq. ammonia dissolves 0·053 grm. of Al_2O_3, and the solubility is raised if ammonium chloride be present. In view of the observations of E. H. Archibald and Y. Habasian, these statements are open for revision. A boiling soln. of ammonium carbonate does not dissolve hydrated alumina, but, according to J. Weeren, if beryllium hydroxide be present, some alumina is dissolved. H. W. Fischer showed that alumina is soluble in an aq. soln. of aluminium chloride. A. Müller-Jacobs said that hydrated alumina is soluble in the alkylamines, and C. Renz said that methylamine, ethylamine, dimethylamine, and diethylamine readily dissolve hydrated alumina, and that the alumina is not precipitated from its soln. in methylamine by ammonia, ammonium chloride, or by acids.

In addition to the previously described mono-, di-, and tri-hydrated aluminas respectively represented by diaspore, idealized bauxite, and gibbsite or hydrargillite, E. J. Maumené said that alumina forms hexahydrates, and A. Villiers claimed to have made hexahydrated alumina, $Al_2O_3.6H_2O$, *i.e. sesquihydrated aluminium hydroxide*, $2Al(OH)_3.3H_2O$, by keeping alumina hydrogel suspended in well-cooled water. V. Zunino said that pentahydrated alumina, $Al_2O_3.5H_2O$, *i.e. monohydrated aluminium hydroxide*, $Al(OH)_3.H_2O$, is formed by the action of moist air on aluminium amalgam. A. Mitscherlich claimed to have made hemihydrated alumina, $2Al_2O_3.H_2O$, *i.e. aluminium dioxyhydroxide*, $Al_2O_2(OH)$. There are also E. Schlumberger's products, $3Al_2O_3.5H_2O$, and $5Al_2O_3.7H_2O$, indicated above. The individuality of none of these hydrates has been estalished.

Ordinary alumina hydrogel is considered by W. B. Hardy [7] to be an irreversible colloid; but R. P. Rose prepared a reversible gel by adding hydrochloric acid to a soln. of aluminium hydroxide in dil. acetic acid. Dil. soln. in propionic, butyric, hydrobromic, hydriodic, or nitric acid also gave an alumina hydrosol, which is reversibly coagulated by adding aluminium salts, or hydrochloric and other acids; but irreversible coagulation occurs when potassium or sodium sulphate is added. A. Müller also prepared the reversible colloid.

A. Tian inferred that when a hydrolytic equilibrium is established slowly, one of the products tends to assume the colloidal state. The hydrolysis will be retarded by two reactions, (i) the ionic reverse of the hydrolysis taking place in the aq. phase; and (ii) the reaction between the soluble product of the hydrolysis and the gel. The second reaction will be slower as the colloidal particles grow larger because less surface per unit mass is available. The total rate of hydrolysis will thus depend on the rate of growth of the colloidal particles. A. Massink has discussed the solubility of aluminium hydroxide.

J. L. Gay Lussac, in 1810, showed that an aq. soln. of aluminium acetate undergoes reversible hydrolysis when the temp. is raised. He said:

> The precipitation of alumina on boiling and the redissolving at a lower temp. are facts which are of interest to the general theory of chemistry and which are rather exceptional. If the precipitation were due to volatilization of the acetic acid, the alumina would not redissolve when the temp. is lowered. As a matter of fact, similar changes can be observed in a strongly acid soln. or in hermetically sealed flasks. Since the precipitation does not depend on the volatilization of the acid, it is evident that it is due to the heat which wrenches apart the mols. of acid and alumina, carrying each out of the sphere of action of the other, and causing their separation. With less heat, the same mols. come within each other's sphere of activity and combine.

In 1853, W. Crum worked with a more dilute and more basic soln. than J. L. Gay Lussac, and found that a white crystalline precipitate of a basic aluminium acetate, $(CH_3COO)_2Al.OH$, is obtained by boiling a conc. soln. of aluminium acetate, $(CH_3COO)_3Al$; and a more protracted boiling completes the hydrolysis. W. Crum said:

> By the continued action of heat on a weak soln. of binacetate of alumina, $Al_2O_3.(CH_3CO_2)_4(OH)_2$, a permanent separation of the constituents of the salt takes place, although no acid escapes and no alumina is precipitated. The properties of the alumina are, at the same time, materially changed. A soln. of binacetate of alumina, diluted so as to contain not more than one part of alumina in two hundred of water, was placed in a closed vessel which was immersed to the neck in boiling water, and kept in that state day and night for ten days. It had then nearly lost the astringent taste of alum, and acquired the taste of acetic acid. Being afterwards boiled in an open capsule, acetic acid was freely given off, and when the boiling had continued about five hours (the loss of water being continually restored), the liquid was found to have retained not more than one-eleventh of its original quantity of acetic acid, or about one eq. to five and a half of alumina.

The colourless, tasteless, and neutral sol—alumina hydrosal—of aluminium hydroxide so obtained was called *meta-alumina*. A colloidal soln., it will be remembered, is one containing a finely divided phase which is prevented from flocculating, so that there is no particular need for the term meta-alumina. According to W. D. Bancroft, water will hydrolyze any salt until the product of the concentrations of the hydrogen and hydroxyl ions reaches a value of about 10^{-14}. If either base or acid is very sparingly soluble, the hydrolysis will run farther than if both are strong electrolytes. Equilibrium will be reached much more rapidly if the soln. is heated. Whether the insoluble base precipitates or remains in colloidal soln. will depend on the conditions of the experiment. That hydrolysis has taken place can be shown in a number of different ways. J. L. Gay Lussac deduced it from seeing the precipitated alumina; and W. Crum, from the change in the taste of the soln. J. Splichal showed that if a trace of sulphuric acid is present as impurity, the hydrosol will be quickly coagulated. S. Murachi and T. Okazaki made the hydrosol by diluting a sat. soln. of aluminium acetate in dil. acetic acid, adding hydrogen dioxide (sodium dioxide, or potassium persulphate) and dialyzing the liquid for about 10 hrs. at 50° 80°.

W. B. Bentley and R. P. Rose consider the sol obtained by digesting freshly precipitated aluminium hydroxide in hot, 8 per cent. acetic acid, to be a sol of basic aluminium acetate. Crum's sol is opalescent, and it can be kept for years without change. The conc. sol is viscous. J. Splichal found that W. Crum's process does not give good results unless the acetate be free from sulphate. E. Schlumberger made colloidal soln. of alumina; and W. Biltz found that the colloidal particles are positively charged because, if, say, 100 volts be passed through the conc. sol contained in a U-tube, in half an hour the liquid near the negative electrode becomes turbid —anodic cataphoresis — and that near the positive electrode becomes clear. Similar remarks apply to colloidal aluminium hydroxide prepared by T. Graham's process, namely, by the dialysis of a soln. of aluminium hydroxide in one of aluminium chloride or acetate. T. Graham's sol acted as a mordant, whereas W. Crum's did not. W. Biltz and W. Geibel made an optical study of the colloidal soln.; and J. H. Hildebrand found that the sol produced by Graham's dialytic process shows submicrons very plainly in the ultramicroscope. S. Kawamura measured the viscosities of the hydrosol. J. H. Gladstone and W. Hibbert determined the f.p. of the sol, and obtained a result indicating a mol. wt. varying from 409·6 to 1073 on the assumption that the method employed for dil. soln. is valid for colloidal soln. The conc. soln. of colloidal alumina is not coagulated by acetic, formic, boric, arsenious, or cyanuric acid, but it is coagulated by hydrochloric, nitric, sulphuric, citric, chromic, or molybdic acid, and by many organic acids. Alkalies have a strong coagulating power; nitrates and chlorides are not very active; while sodium, magnesium, or calcium sulphate coagulates the colloid very quickly. It is therefore probable, added T. Graham, that the extraordinary coagulating action of salts upon hydrated alumina must prevent the latter substance from ever appearing in a soluble state when liberated from combination by means of a base. S. Wosnessensky found colloidal alumina is not coagulated by single electrolytes excepting lime-water or baryta-water; but marked coagulation occurred with bi- or ter-valent metal salts and alkali hydroxides. S. Utzino found that the maximum stability of colloidal soln. of aluminium hydroxide in the presence of glucose does not occur with the finest state of subdivision.

J. B. Cammerer[8] found that aluminium hydroxide is soluble in a 2 per cent. soln. of hydrogen dioxide. When the product is conc. by evaporation, it furnishes a syrupy liquid which yields a crystalline mass, sparingly soluble in cold water. The soln. had an acid reaction, but it is not clear whether the original soln. of hydrogen peroxide was free from acid. P. R. Jourdain showed that hydrogen dioxide is contained in the product obtained by the oxidation of aluminium amalgam in air. A. Terni found that when an excess of 30 per cent. hydrogen doxide is added to a soln. of aluminium hydroxide in 50 per cent. potassium hydroxide, there is obtained an amorphous white precipitate having the composition $Al_2O_3.Al_2O_4.10H_2O$, which reacts as if it were a true **aluminium peroxide**. It is assumed that Al_2O_4 is the initial product of the oxidation of aluminium hydroxide by hydrogen dioxide, and that this product is gradually hydrolyzed to furnish the oxide $Al_2O_3.Al_2O_4.10H_2O$. J. A. Wilkinson prepared aluminium peroxide by adding sodium dioxide to a soln. of an aluminium salt until the precipitate first formed just dissolved, and then adding hydrogen peroxide. The precipitated aluminium peroxide, dried at 110°, gave no signs of phosphorescence when exposed to the cathode rays.

§ 12. The Aluminates

The solubility of aluminium hydroxide in acids results in the formation of salts whose characters show that aluminium hydroxide is a weak base; on the other hand, the solubility of the hydroxide in a soln. of alkali hydroxide, and the formation of the so-called alkali aluminate can be attributed to the feeble acidic properties of aluminium hydroxide. Otherwise stated, *aluminium hydroxide is amphoteric*; and, in aq. soln., it is assumed to be ionized in two ways, namely:

$$\mathrm{Al(OH)_3}\begin{cases}\rightleftharpoons \mathrm{Al}^{\cdots}+3\mathrm{OH}' \\ \rightleftharpoons \mathrm{H}^{\cdot}\ \ +\mathrm{H_2AlO_3}'\rightleftharpoons \mathrm{H}^{\cdot}+\mathrm{H_2O}+\mathrm{AlO_2}'\end{cases}$$

J. K. Wood[1] was unable to determine the basic constant because, although a soln. with 0·0375 mol of aluminium chloride is hydrolyzed to the extent of 4 per cent. at 25°, there is no means of establishing the assumed mode of hydrolysis, $\mathrm{AlCl_3+H_2O=HCl+Al(OH)Cl_2}$. He showed that a $\frac{1}{10}N$-soln. of sodium metaluminate is hydrolyzed to the extent of 35 per cent. at 25°; if so, the hydrolysis constant is $1{\cdot}2\times10^{-13}$, and the acidic ionization constant is $6{\cdot}3\times10^{-13}$. G. Carrara and G. B. Vespignani found aluminium hydroxide to be more energetic as a base than as an acid; they also measured the conductivity and speed of hydrolysis of methyl acetate by some metal hydroxides and found that the order of decreasing activity is Mg, Cu, Zn, Cd, Al, Fe, so that, contrary to E. A. Schneider, they believe that ferric hydroxide is not a more energetic base than aluminium hydroxide. Working with crystalline aluminium hydroxide, R. E. Slade also found that aluminic acid is stronger as a base than as an acid, and its ionization constant, K, is at least 10^{-10}, the same order as that of boric acid; and working with colloidal aluminium hydroxide, W. Blum obtained for the acid constant $K=10^{-8\cdot3}$. According to J. Heyrovsky, the process by which aluminium hydroxide dissolves in alkalies is not the same as if it could send into soln. one, two, or three of its hydrogen atoms as ions, and thus react like, say, phosphoric acid. It does not neutralize bases like an acid by means of hydrogen ions, but rather does it remove hydroxyl ions and form complex anions, $\mathrm{Al(OH)_3+OH'=Al(OH)_4}'$, like compounds do when redissolving in an excess of reagents, *e.g.* $\mathrm{AgCy_2}'$, $\mathrm{HgI_4}''$, etc. It neutralizes not by its acidity but by its affinity for hydroxyl ions. The hydrolysis of aluminates is then not affected by the scarcity of hydrogen ions from aluminic acid, but by the incompleteness of the complex ion formation.

A. Hantzsch found that the mol. conductivity of sodium aluminate soln. continually increases with time, and this is taken to show that a fairly rapid hydrolysis occurs with time although no precipitation occurred in 96 hrs. The first product of the hydrolysis is alumina hydrosol, which then changes into the gel form, and then changes to crystalline aluminium hydroxide. G. Carrara and G. B. Vespignani said that the degree of hydrolysis of potassium aluminate is fourteen times that of aluminium sulphate in aq. soln.

A number of salts has been isolated from soln. of aluminium or aluminium hydroxide in alkali-lye, and some appear to be well-defined chemical individuals —salts of metaluminic acid, $\mathrm{HAlO_2}$. There has been some discussion as to whether the alleged alkali metaluminate in soln. is a myth. E. G. Mahin and co-workers, for example, hold that the colloidal properties of aluminium hydroxide play such an important part in conditioning its solubility in bases, that there is room for doubt as to whether the alleged aluminates, as definite salts, exist at all.

E. G. Mahin's arguments rest on (i) the fact that the reaction between ammonium nitrate and sodium aluminate precipitates a slightly greater quantity of aluminium hydroxide than is represented by the assumption that an aluminate, $\mathrm{NaAlO_2}$, is involved in the reaction: $\mathrm{NaAlO_2+NH_4NO_3=NH_4AlO_2+NaNO_3}$, followed by the instantaneous hydrolysis of the ammonium aluminate: $\mathrm{NH_4AlO_2+2H_2O=NH_4OH+Al(OH)_3}$, where the ratio $\mathrm{[NH_4NO_3]/[Al_2O_3]}$ is 2 : 1. It is therefore assumed that the precipitation is due to a coagulation of alumina hydrosol. As W. Blum showed, there are some disturbing factors involved —*e g.* spontaneous decomposition—which invalidate the conclusion. (ii) In the electrolysis of aq. soln. of the alleged aluminate the ratio between the oxygen evolved and the aluminium hydroxide precipitated should be constantly 1 : 2. E. G. Mahin, in some cases, obtained rather more aluminium hydroxide than is required on the assumption that it is wholly a product of electrolysis but the disturbances due to re-soln. of some of the precipitate by the anode liquor, and the possible spontaneous decomposition of the aluminate soln. render the argument inconclusive.

A. B. Prescott, and A. Cavazzi maintained that since a mol of sodium hydroxide is needed for the dissolution of a mol of aluminium hydroxide, no matter whether the soln. be dil. or conc., the soln. must contain the metaluminate. W. Herz found that while freshly precipitated aluminium hydroxide behaves in this way, if the hydroxide be dried, an ortho-aluminate of the composition Na_2AlO_3 is formed, but R. E. Slade found that the ratio of Na : Al in the solubility determinations ranges from 2 : 1 to 10 : 1 according to the conditions of precipitation, and the mode and duration of the drying of the hydroxide. The solubility ratio, therefore, is not a good criterion for deducing a formula for the salt in soln., and there is no evidence for assuming that the soln. contains AlO_3'''-ions; colloidal alumina is always present as an unstable phase under these conditions. F. M. Lyte argued that in dil. soln. the aluminate is $NaAlO_2$, because six mols react with a mol of aluminium sulphate precipitating 8 mols of aluminium hydroxide, $Al_2(SO_4)_3+6NaAlO_2+12H_2O=3Na_2SO_4+8Al(OH)_3$; in conc. soln., he said, it is probable that some other aluminate is present. J. K. Wood's solubility determinations of aluminium and of aluminium hydroxide in soln. of sodium hydroxide after allowing for a slight excess of alkali over the amount required to form aluminate owing to the partial hydrolysis of the salt, agree with the assumption that sodium metaluminate is formed, but not the ortho-salt. Observations on this subject were also made by H. St. C. Deville, A. Ditte, F. Russ, A. Glässner, etc. According to G. Carrara and G. B. Vespignani, the aq. soln. contains only the meta-aluminate, even if a large excess of potassium hydroxide is present. A. A. Noyes and W. R. Whitney determined the lowering of the f.p. by soln. of the sodium meta-aluminate, and assuming that both sodium hydroxide and sodium aluminate are completely ionized, the soln. of alumina in sodium hydroxide would give the same f.p. as sodium hydroxide alone if the aluminate be $NaAlO_2$, but a different f.p. if it be $(NaAlO_2)n$, because two ions would be produced by a mol. of either NaOH or $NaAlO_2$; three ions, by $Na_2Al_2O_4$; four ions, by $Na_3Al_3O_6$; etc. Observation showed that the f.p. of a $0{\cdot}227N$-soln. of potassium hydroxide was not altered by the dissolution of $\frac{1}{3}$, $\frac{2}{3}$, or one gram-atom of aluminium; a $0{\cdot}465N$-soln. was not changed by $\frac{1}{6}$, $\frac{1}{2}$, or $\frac{2}{3}$-gram-atom of aluminium; and $0{\cdot}233N$-soln. of sodium or potassium hydroxide was not changed by $\frac{1}{2}$ and $\frac{2}{3}$ mol of aluminium hydroxide or $\frac{1}{2}$ and $\frac{2}{3}$ gram-atom of aluminium. Assuming that the hydrolysis of the soln. is insignificant, the work of A. A. Noyes and W. R. Whitney shows that the formula of the alkali aluminate in soln. is $MAlO_2$. If hydrolysis is appreciable, then, as E. G. Mahin and co-workers have shown, the conclusion is invalid because each mol. of $NaAlO_2$ would furnish three ions: $NaAlO_2+H_2O \rightleftharpoons Na^{\cdot}+OH'+HAlO_2$, which would modify the f.p. accordingly. R. E. Slade's observations on the f.p. of the soln. also led him to conclude that the soln. of alkali aluminate contain mol. of $NaAlO_2$. E. G. Mahin and co-workers inferred that because the heat of soln. of aluminium hydroxide in 1000 times its eq. of sodium hydroxide, is very small, being roughly only 0·864 Cal. per mol., the thermo-chemical datum lends no support to the assumption that a compound is formed during the process. But, as W. Blum pointed out, if the heat of soln. of aluminium hydroxide is negative, as is the case with boric acid, this argument is of no moment. R. E. Slade's observations were confirmed by J. Heyrovsky for sodium and ammonium hydroxides.

Conductivity determinations of soln. of alkali aluminate, by R. E. Slade and W. G. Polack, W. Blum, J. H. Hildebrand, A. Hantzsch, and G. Carrara and G. B. Vespignani, show that the salt of a monobasic acid is present undergoing hydrolysis; no change in conductivity occurs without the simultaneous deposition of aluminium hydroxide. J. H. Hildebrand, and W. Blum have measured the variation in the conc. of the $H^{\cdot}$-ion as alkali-lye is progressively added to soln. of aluminium chloride while aluminium hydroxide is being precipitated, and then dissolved in the excess of alkali-lye. The results are indicated in Fig. 52. The neutralization curve with hydrochloric acid and sodium hydroxide is given for reference. Here, the point of inflexion represents the neutralization of the soln. With aluminium chloride and potassium and sodium hydroxides, say the latter, *A* represents the commencement of the precipitation; *B*, the completion of the precipitation; and *C*, the completion of the soln. of the precipitate. From *A* to *B*, therefore, $AlCl_3+3NaOH=Al(OH)_3+3NaCl$; and from *B* to *C*, $Al(OH)_3+NaOH=2H_2O+NaAlO_2$. Consequently, since $bc=\frac{1}{3}ab$, the results are in agreement with the assumption that the metaluminates $NaAlO_2$ and $KAlO_2$ exist in aq. soln., and are in opposition to the hypothesis that any marked proportion of aluminium hydroxide is present. The curve also shows that the precipitation of aluminium hydroxide begins when the H'-ion conc. is about 10^{-3}, and ends when that conc. is 10^{-7}.

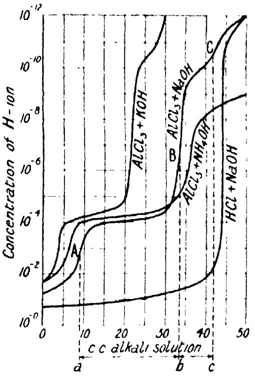

FIG. 52. Variation in the Concentration of the H'-ion during the Precipitation of Aluminium Hydroxide, and the Dissolution of the Precipitate in Alkali-lye (25°).

N. G. Chatterji and N. R. Dhar showed that the conductivity of a soln. of sodium hydroxide is not appreciably changed by the addition of aluminium hydroxide, and hence they conclude that such soln. are cases of true peptization, and not of chemical combination. J. H. Hildebrand failed to detect colloidal particles in aluminate soln. by means of the ultramicroscope, but if the soln. is hydrolyzed some colloidal alumina should be present. Hence, as R. E. Slade and W. G. Polack have said, the ultramicroscope affords no conclusive evidence either way.

E. T. Allen and H. F. Rogers prepared a microcrystalline powder of pentahydrated **lithium hydrometaluminate,** $LiH(AlO_2)_2.5H_2O$, by dissolving aluminium in an aq. soln. of lithium hydroxide free from carbonate. The product was washed once in cold water, then with alcohol, with ether, and then dried over calcium chloride. It is more stable towards water than sodium or potassium aluminates, being decomposed only after continued boiling. It is sparingly soluble in cold water. No lithium aluminate other than this salt could be prepared in soln. When kept two weeks in vacuo over sulphuric acid at a summer's temp., the trihydrate, $LiH(AlO_2)_2.3H_2O$, was formed. Z. Weyberg obtained birefringent (possibly rhombic), rounded granules of **lithium metaluminate,** $LiAlO_2$, by fusing for several hours a mixture of silica, alumina, and lithium carbonate, in the proportions $2SiO_2 : Al_2O_3 : Li_2O$, with an excess of sodium sulphate. F. M. Jäger and A. Simek made the metaluminate by fusing a mixture of alumina and lithium carbonate at 900°, and then at 1200°. They did not succeed in melting the carbonate at temp. up to 1625°; but R. Ballo and E. Dittler said that lithium metaluminate melts between 1900° and 2000°, and is homogeneous on cooling. The compound can retain about 12·5 molar per cent. of alumina in solid soln., but beyond that proportion corundum crystallizes out. F. M. Jäger and A. Simek found that it forms microscopic, hexagonal or octagonal, crystals with a pronounced double refraction; the indices of refraction are 1·604 and 1·615 for the *D*-line; and the sp. gr. is 2·554 at 25·1°.

J. J. Berzelius was unable to fuse a mixture of alumina and sodium carbonate on charcoal before the blowpipe flame, although he said that combination occurs. F. G. Schaffgotsch found that a mol of alumina fused with an excess, or, according to E. Mallard, with an eq. amount of sodium carbonate, rapidly expels rather more than a mol of carbon dioxide. R. C. Wallace showed that although the gas is driven off at 1100° to 1200°, melting does not occur under 1800°. The product on cooling is crystalline, and usually of a bright red colour owing to the presence of a trace of iron abstracted from the crucible. With increasing proportions of alumina, the m.p.

is raised so that a mixture with 81·1 per cent. of alumina is only partially fused at 1950°. H. Grüneberg and J. Vorster heated a mixture of sodium chloride and alumina in a current of steam. The fused product furnishes a white enamel with a conchoidal fracture. It melts readily; dissolves easily and completely in cold water; and weathers on exposure to air, forming a surface efflorescence of sodium carbonate. There is, here, nothing to show that a chemical individual is produced. W. G. Mixter gives for the heat of formation from amorphous alumina, $Na_2O + Al_2O_3 = 2NaAlO_2 + 40{\cdot}00$ Cals., and from crystalline alumina, 30·00 Cals. C. Tissier reported aluminates, $3Na_2O.Al_2O_3$, *i.e.* Na_3AlO_3, sodium orthoaluminate; $3Na_2O.2Al_2O_3$; and $Na_2O.Al_2O_3$ to be formed in the dry way; but, with no other test for the individuality of a compound than fusing molar proportions of the constituents, an indefinitely large number of such compounds could be obtained. J. A. Wilkinson said that sodium aluminate fluoresces and phosphoresces under the cathode rays in the same way as does aluminium oxide made by burning the metal in air. The residue is coloured deep blue, presumably by the soln. of sodium in the aluminate. The preparation of aq. soln. of sodium aluminate from bauxite, etc., and the general properties of the soln. have been previously described. A. Cavazzi, and J. G. Bogussky and J. Zaljesky obtained a viscid mass by evaporating the aq. soln. of sodium aluminate, but E. T. Allen and H. F. Rogers said that by repeatedly digesting with alcohol the conc. soln. containing equimolar proportions of Al_2O_3 and Na_2O, a hard mass, possibly, dihydrated **sodium aluminate,** $NaAlO_2.2H_2O$, is formed. F. Goudrian studied the system $Na_2O-Al_2O_3-H_2O$ at 30°, and found two stable salts, hexadecahydrated **sodium trialuminate,** $4Na_2O.3Al_2O_3.16H_2O$, in diamond-shaped crystals; and decahydrated **sodium monoaluminate,** $4Na_2O.Al_2O_3.10H_2O$, in needle-like crystals. Both salts are very hygroscopic, and form incongruent sat. soln. The conditions of equilibrium are illustrated by Fig. 53. *A* is a triple point representing the coexisting phases $Al_2O_3.3H_2O$; $4Na_2O.3Al_2O_3.16H_2O$; and soln.; *G*, the phases $4Na_2O.3Al_2O_3.16H_2O$; $4Na_2O.Al_2O_3.10H_2O$; and soln.; and *H*, the phases $4Na_2O.Al_2O_3.10H_2O$; $NaOH.H_2O$; and soln. The line *BA* represents a soln. in equilibrium with the solid phase $Al_2O_3.3H_2O$; the line *AG*, with the solid phase $4Na_2O.3Al_2O_3.16H_2O$; *GH*, with the solid phase $4Na_2O.Al_2O_3.10H_2O$; and *HI*, with the solid phase $NaOH.H_2O$. The dotted curves *Ca*, *Cb*, and *Cc* represent metastable states. R. Fricke, and E. Grobet have made observations on this subject. C. Matignon found the aluminate, $NaAlO_2$, melted at 1650°, and is formed from a mixture of alumina and sodium carbonate at 1100°–1200°. Aluminates of the type $(n+1)Na_2O.Al_2O_3$ dissociate below 1650° with the loss of sodium oxide until $Na_2O.Al_2O_3$ is obtained.

FIG. 53. Equilibrium with the Ternary System, $Na_2O-Al_2O_3-H_2O$, at 30°.

A grey mass, soluble in water and acids, is obtained by fusing alumina with potassium hydroxide or carbonate; and soln. of potassium aluminate were prepared by A. B. Prescott, and A. Cavazzi as previously described, by the action of a soln. of potassium hydroxide on aluminium or alumina. O. Unverdorben evaporated a boiling soln. to a small bulk, extracted the excess of uncombined potassium hydroxide with alcohol, and obtained a residue with equimolar proportions of K_2O and Al_2O_3. E. Frémy precipitated a soln. of potassium aluminate with ammonium carbonate, and concentrated, in vacuo, the aq. soln. obtained by leaching a fused mixture of alumina and potassium hydroxide, and obtained a crystalline mass, which, after purification by re-crystallization from water, contained $KAlO_2.H_2O$. According to E. T. Allen and H. F. Rogers, hard, nodular crystals of sesquihydrated **potassium aluminate,** $KAlO_2.1\frac{1}{2}H_2O$, separate when the soln. obtained by dissolving aluminium in 10 per cent. aq. soln. of potassium hydroxide, is evaporated in vacuo over sulphuric acid. If the alkali be not in excess, the aluminate is hydrolyzed and crystalline aluminium hydroxide is deposited, whilst the metal continues to dissolve indefinitely instead of in the proportion corresponding with A. Cavazzi's equation: $2Al+2KOH+2H_2O=2KAlO_2+3H_2$. The salt is insoluble in alcohol; soluble in water with partial hydrolysis; it is hygroscopic, and is decomposed by carbon dioxide. The aq. soln. was found by E. Frémy to have an alkaline reaction, and a caustic taste; he also said that when the salt has been dehydrated by heating, it is no longer completely soluble in water. F. Braun measured the compressibility of the soln. Many properties of the aq. soln. have already been indicated. P. A. von Bonsdorff noted that the aq. soln. is decomposed and aluminium hydroxide precipitated by carbon dioxide. L. B. G. de Morveau, C. F. Bucholz, and J. W. Döbereiner showed that acids and ammonium salts precipitate aluminium hydroxide, while aq. soln. of the alkaline earths precipitate the corresponding aluminates, quantitatively, according to F. Kuhlmann, in the case of lime-water. F. W. Bergstrom made **potassium amminoaluminate,** $Al(NHK)(NH_2)_2$, by the action of a soln. of potassium amide in liquid ammonia on amalgamated aluminium.

W. Blum found that an aq. soln. of ammonium hydroxide dissolves a small but appreciable amount of alumina, even when the soln. is just alkaline to phenolphthalein with a H˙-ion conc. of 10^{-9}; and, as previously indicated, E. H. Archibald and Y. Habasian measured the solubility of aluminium hydroxide in that menstruum. By analogy with the alkali aluminates, it is here assumed that the soln. contains partially hydrolyzed **ammonium aluminate,** NH_4AlO_2. W. Blum's determination of the H˙-ion conc. during the precipitation of aluminium hydroxide by adding ammonium hydroxide does not give any definite evidence of the formation of ammonium aluminate, because of the low alkalinity of the aq. soln. The maximum conc. of the ammonium aluminate in soln. is obviously dependent on the alkalinity of the resulting soln., and its ability to repress the hydrolysis of the aluminate. C. Renz dismissed the possibility of the existence of ammonium aluminate even though by an indirect method—dissolution of aluminium hydroxide in baryta water, and the subsequent addition of ammonium sulphate—he was able to obtain a clear soln., free from barium salt and sulphates, which contained 0·2 grm. alumina per 100 c.c. The fact that freshly precipitated aluminium hydroxide is readily soluble in organic amines is in agreement with the hypothesis that ammonium aluminate is formed in soln. J. Brezina reported the formation of tetramethylammonium aluminate.

J. J. Berzelius prepared what has been called *cupric aluminate*, of unknown composition, by treating the double fluoride of aluminium and copper with ammonia. An excess of ammonia does not extract the cupric oxide. According to J. A. Hedvall and J. Heuberger, when cupric oxide and aluminium oxide are heated together, a reaction starts at about 700° and proceeds quickly between 750° and 850°. The product, which forms a chocolate-coloured powder, has, when freed from unchanged oxides, the composition $CuO.Al_2O_3$, and is therefore of the spinel type. It is very resistant to solvents in general. When fused with potassium chloride, it undergoes partial decomposition, and the undecomposed portion crystallizes, on cooling, in well-formed cubes and octahedra. A. C. Becquerel separated aq. soln. of cupric nitrate and alkali aluminate by a collodion film, and obtained blue crystals admixed with cupric hydroxide on the membrane. A purple of Cassius in which the stannic oxide is replaced by alumina has been made—*vide* purple of Cassius (3. 23, 11).

The early workers, F. C. Achard, A. L. Lavoisier, and J. P. J. d'Arcet,[2] tried heating mixtures of lime and alumina, and with the furnace temp. then available, they were able to fuse mixtures of alumina with 25 to 50 per cent. of lime, but not mixtures with a higher proportion of lime. N. G. Sefström found mixtures $3CaO+Al_2O_3$, and $CaO+Al_2O_3$, could be fused to vitreous masses. Several unmethodical observations have been made on the relations between lime and alumina. J. J. Ebelmen obtained corundum free from lime by fusing alumina with calcium chloride and boric oxide; similar results were obtained by using baryta in place of the calcium compound. H. St. C. Deville, C. Tissier, W. Heldt and E. Landrin examined the products obtained by heating various mixtures of lime and alumina—the two last-named from the point of view of cements. E. Solvay found that a heated mixture of calcium chloride and alumina react in dry air with the evolution of chlorine, and in moist air with the evolution of hydrogen chloride. Similar results were obtained by M. A. Gaudin with mixtures of barium chloride and alumina, and he made **barium aluminate** by the action of steam on a red-hot mixture of barytes, carbon, and alumina. G. Arth made barium aluminate, to be used as a de-encrusting agent, by heating barytes with bauxite and extracting the mass with water. The soln. deposits barium hydroxide until its sp. gr. is 1·029, when barium aluminate appears. E. S. Shepherd, G. A. Rankin, and F. E. Wright explored the binary system $CaO-Al_2O_3$, and they found evidence of the existence of compounds with the molar ratio $CaO : Al_2O_3 = 3 : 1$, $1 : 1$, $5 : 3$, and $3 : 5$. The results are indicated in Fig. 54; they have been extended to ternary systems with silica, and applied to the chemical changes which occur during the manufacture and use of Portland cement. E. D. Campbell studied the formation of mixed crystals of calcium ferrite and aluminate. P. H. Bates investigated the cementing qualities of the four **calcium aluminates** made by heating alumina and lime in the necessary proportions. The so-called *satin-white* is a mixture of calcium aluminate with calcium sulphate. Its preparation is described by A. Cobenzl, etc. Rochette Frères prepared calcium aluminate almost free from other oxides by heating bauxite, or other aluminium ore, with lime and carbon or silicon, aluminium or calcium carbide in an electric furnace, whereby all the foreign oxides are reduced to the metallic state.

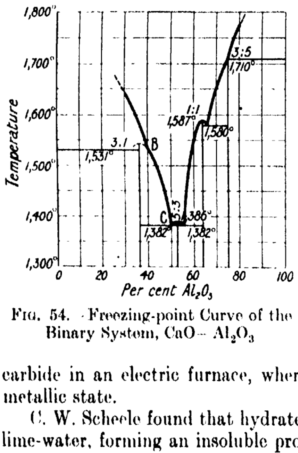

FIG. 54.—Freezing-point Curve of the Binary System, $CaO-Al_2O_3$

C. W. Scheele found that hydrated alumina removes the whole of the lime from lime-water, forming an insoluble product. F. Kuhlmann added lime-water to an aq. soln. of potassium aluminate, and precipitated calcium aluminate, potassium hydroxide remained in the mother-liquor; likewise, O. Unverdorben precipitated calcium aluminate by adding a soln. of potassium aluminate to one of calcium chloride; and E. Pelouze, by adding calcium chloride to a soln. of alum and potassium hydroxide. L. N. Vauquelin prepared strontium and barium aluminates by the action of boiling strontia-water or baryta-water on aluminium hydroxide; and O. Unverdorben obtained barium aluminate as a gelatinous precipitate by adding a soln. of barium chloride to one of potassium aluminate; but E. Beckmann said that a soln. of baryta-water and aluminium chloride reacts: $2AlCl_3+3BaO+Aq. = Al_2O_3+3BaCl_2+Aq.$ J. Heyrovsky prepared dil. soln. of aluminates of calcium, strontium, and barium, and measured their f.p. P. Miguet patented a process for making the aluminates of the alkaline earths from clays. H. le Chatelier found that when soln. of alkali aluminate and lime-water are mixed, crystallization begins very quickly and continues for hours; the product is a mass of crystals which are optically active. The composition corresponds with henicosihydrated **tetracalcium dialuminate**, $Ca_4Al_2O_7.21H_2O$, *i.e.* $4CaO.Al_2O_3.21H_2O$, and he said that at 40° the dodecahydrate is formed, and the compound becomes anhydrous when calcined. H. le Chatelier made the crystals illustrated by Fig. 55, by fusing a mixture of one molar part of alumina with 1·5 to 2 molar parts of calcium oxide. Unfortunately, said he, the fused masses are not completely crystallized, and even after recalcination a vitreous part remains which causes a little uncertainty as to the exact composition of the crystallized aluminate. The work of E. S. Shepherd, G. A. Rankin, and F. E. Wright, Fig. 54, shows that **tricalcium dialuminate,** $Ca_3Al_2O_6$, or $3CaO.Al_2O_3$, is unstable at its m.p., so that there is no true m.p., although all is completely fused at 1550°. Both CaO and $3CaO.Al_2O_3$ separate at 1531°, while along the liquidus curve *BC*, Fig. 54, the compound $3CaO.Al_2O_3$ is the stable phase. Consequently, it is probable that both N. G. Sefström, and C. Tissier made this compound. E. D. Campbell found that the tricalcium aluminate may be crystallized from a soln. of calcium oxide in $5CaO.3Al_2O_3$ as solvent provided the conc. of the calcium oxide at the beginning of the crystallization is sufficient to form the tricalcium aluminate with all the alumina. E. S. Shepherd, G. A. Rankin, and F. E. Wright showed that the crystals belong to the cubic system; the fracture is conchoidal; the hardness is 6; and the isotropic crystals have an index of refraction 1·710±0·001 with Na-light. This compound is an important constituent of Portland cement clinker. When in contact with water, it yields the amorphous hydrate, $3CaO.Al_2O_3.nH_2O$, which slowly crystallizes. H. le Chatelier represented the hydration process by the equation: $3CaO.Al_2O_3+Ca(OH)_2+Aq.=Al_2O_3.4CaO.12H_2O$. The effect of the hydration is shown in Fig. 56. E. Candlot showed that the formula of the hydrated salt is more probably $3CaO.Al_2O_3.nH_2O$. C. Lowig claims to have made it by boiling alkali aluminate with lime-water; but E. T. Allen and H. F. Rogers showed that by adding an aq. soln. of potassium aluminate to hot lime-water, the hexahydrated salt, $3CaO.Al_2O_3.6H_2O$, is precipitated. They also prepared hexahydrated **tristrontium dialuminate,** $Sr_3Al_2O_6.6H_2O$, by boiling aluminium with conc. strontia-water; hydrogen is evolved, but no further action then occurs, and in the cold, the metal dissolves, and the salt separates. The same compound is better obtained by adding a soln. of potassium aluminate, containing an excess of potassium hydroxide, to a hot soln. of strontium chloride or hydroxide; it forms a white, heavy, granular, crystalline powder sparingly soluble in water, by which it is only slowly decomposed, and it is sensitive to the action of carbon dioxide. It resembles closely the corresponding calcium compound. E. Beckmann obtained hydrated **tribarium dialuminate,** $Ba_3Al_2O_6.7·5$ to $11H_2O$, or $3BaO.Al_2O_3.7·5$ to $11H_2O$, by evaporating a soln. of a mol of dibarium dialuminate, 16 mols of barium hydroxide in 30 parts by weight of boiling water. The badly-developed crystals have water

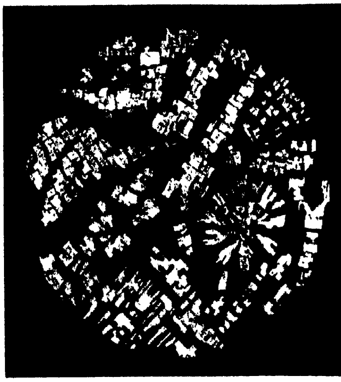

FIG. 55. Crystals of Tricalcium Aluminate, $Ca_3Al_2O_6$, or $Ca_3Al_4O_9$.

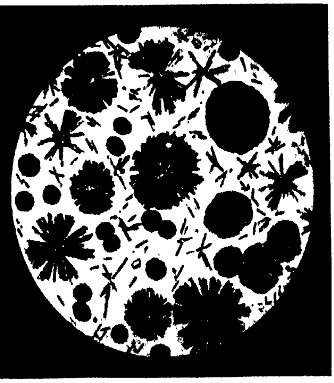

FIG. 56. Hydration of Tricalcium Dialuminate.

of crystallization dependent on the temp. of evaporation. The salt is sparingly soluble in cold water, and 100 parts of boiling water dissolve 6·7 parts of salt; the aq. soln. on evaporation gives a mixture of barium hydroxide and dibarium dialuminate. At 100°, the salt has 6·5-7·0H_2O; at 150°, 6H_2O; at 165°, 3H_2O; at 225°, 2H_2O; and much water is retained by all the hydrated barium aluminates at the m.p. of potassium dichromate, a temp. at which barium hydroxide becomes anhydrous baryta. No oxygen is absorbed if the salt is heated in a current of air; but in a stream of carbon dioxide, two mols of the gas are absorbed.

C. Zulkowsky obtained a porcelain-like mass by sintering a mixture of a mol of alumina with two mols of calcium oxide at about 1500°. When treated with water, it breaks down into calcium and aluminium hydroxides: $2CaO.Al_2O_3+4H_2O=Al_2O(OH)_4+2Ca(OH)_2$. E. Dufau could not prepare **dicalcium dialuminate,** $2CaO.Al_2O_3$, or $Ca_2Al_2O_5$; nor did E. S. Shepherd, G. A. Rankin, and F. E. Wright obtain any evidence of the formation of such a compound in their study of the binary system, Fig. 52. E. T. Allen and H. F. Rogers obtained the hexa- or heptahydrate, $Ca_2Al_2O_5.6$ or $7H_2O$, by dissolving aluminium in lime-water kept saturated with calcium hydroxide. After some days, crystals of the salt appear on the metal; these are scraped off and washed with water, then with alcohol, and finally in ether. The salt is very sparingly soluble in water and very slowly decomposed by that menstruum. C. Zulkowsky heated a mixture of the 2 mols of baryta with one of alumina and obtained what he regarded as **dibarium dialuminate,** $2BaO.Al_2O_3$, or $Ba_2Al_2O_5$, which, he said, behaves like the calcium salt towards water. According to E. T. Allen and H. F. Rogers, aluminium dissolves vigorously in hot conc. baryta-water, forming a heavy crystalline powder which, after washing with cold water, and then with alcohol, has the composition $Ba_2Al_2O_5.5H_2O$, or $2BaO.Al_2O_3.5H_2O$. It is moderately soluble in water, and easily decomposed thereby. E. Beckmann boiled precipitated aluminium hydroxide with more than the calculated quantity of baryta-water; filtered the soln.; and on evaporation obtained crystals, which, according to A. Fock, are triclinic pinacoids with axial ratios and angles $a:b:c=0{\cdot}8545:1:0{\cdot}9888$ and $\alpha=99°\ 20{\cdot}5'$, $\beta=91°\ 52'$, and $\gamma=109°\ 26{\cdot}5'$. The crystals decrepitate if rapidly heated, and when slowly heated to 125°, lose no appreciable quantity of water; at 155°, they lose 2 mols of water; at 180°, they gradually lose more water, but at 300°, one mol of water is still retained and is expelled only at a red heat. The salt is sparingly soluble in cold water, and 100 parts of hot water slowly dissolve 5 parts of the salt. The soln. is more or less turbid, and reacts alkaline, but on crystallization furnishes the original salt. The soln. is decomposed by carbon dioxide, and the dry salt absorbs that gas.

According to E. S. Shepherd, G. A. Rankin, and F. E. Wright, the well-defined maximum in the f.p. curve of lime and alumina, Fig. 54, at 1386° corresponds with the formation of **pentacalcium hexaluminate,** $5CaO.3Al_2O_3$, or $Ca_5Al_6O_{14}$. The eutectic $3CaO.Al_2O_3-5CaO.3Al_2O_3$ occurs at 1382° with 51 per cent. of alumina. The crystals are isotropic and belong to the cubic system; the fracture is conchoidal; the sp. gr. is 2·828 at 25°/25°; the hardness 5; and the refractive index for Na-light $1{\cdot}608 \pm 0{\cdot}002$—the refractive index of a glass of the same composition is 1·662. Solid soln. were looked for but not found. This compound also occurs in an unstable form which readily changes to the isotropic form. It is obtained in radial, fibrous aggregates by rapid cooling; the hardness is 5; the refractive index $\alpha=1{\cdot}687 \pm 0{\cdot}002$; $\gamma=1{\cdot}692 \pm 0{\cdot}002$; the birefringence is weak and negative. The crystal form is probably rhombic. In contact with water, this compound decomposes, producing amorphous $3CaO.Al_2O_3.nH_2O$, and aluminium hydroxide. G. Friedel heated in a platinum-lined, steel tube to 500°, six grms. of calcium oxide with a soln. of aluminium chloride (eq. to 3 grms. of metal) in 40-55 c.c. of water. The thin, tabular, rhombic crystals of trihydrated **tetracalcium hexaluminate,** $4CaO.3Al_2O_3.3H_2O$, or $Ca_4Al_6O_{13}.3H_2O$, so obtained had the axial ratios $a:b:c=0{\cdot}5176:1:0{\cdot}7463$. No sign of a tetracalcium hexaluminate appears on the equilibrium diagram, Fig. 54.

E. S. Shepherd, G. A. Rankin, and F. E. Wright prepared the spinel analogue

calcium metaluminate, $Ca(AlO_2)_2$, or $CaO.Al_2O_3$, and it appeared as a maximum on the f.p. curve, Fig. 54, at 1587°. The eutectic $5CaO.3Al_2O_3-CaO.Al_2O_3$ is at 1382° and 53 per cent. Al_2O_3. Hence, the compound was probably made by N. G. Sefström, C. Zulkowsky, Rochette Frères, H. St. C. Deville, and J. J. Ebelmen. By heating a mixture of 100 parts of alumina and 60 parts of calcium oxide to a high temp. in an electric furnace, E. Dufau obtained this same compound in colourless needles, but he did not succeed in making polycalcium aluminates in this way. The excess of admixed calcium oxide is removed by boiling the powdered mass with alcohol containing one per cent. of nitric acid, and washing the residue with alcohol and finally with ether. E. S. Shepherd and co-workers did not obtain single crystals of this compound; the elongated needles and prisms are intricately twinned individuals. The birefracting crystals belong either to the monoclinic or triclinic systems—probably the former. E. Dufau gave 3·671 for the sp. gr. at 20°, and he said that the crystals are softer than glass. E. S. Shepherd and co-workers said that the hardness is about 6·5; the extinction oblique; the birefringence strong, about 0·002; and the refractive indices for Na-light are $\alpha=1{\cdot}641\pm0{\cdot}002$; $\beta=1{\cdot}654\pm0{\cdot}003$; and $\gamma=1{\cdot}661\pm0{\cdot}002$. Calcium metaluminate like the analogous beryllium salt, chrysoberyl, and like calcium chromate, and calcium ferrite, does not belong to the group of spinels. According to E. Dufau, the compound is quite stable in dry air. C. Zulkowsky said that with water it is decomposed and sets hydraulically $Ca(AlO_2)_2+2H_2O=2AlO(OH)+Ca(OH)_2$: E. S. Shepherd stated that it is attacked slowly by cold and rapidly by hot water, forming amorphous $3CaO.Al_2O_3.nH_2O$, and $Al(OH)_3$. According to E. Dufau, it is readily soluble in hydrochloric acid, and but slightly affected by nitric, sulphuric, or hydrofluoric acid. Fluorine attacks it only when assisted by heat; but chlorine, bromine, iodine, or sulphur has no action at the softening temp. of glass. It is decomposed when heated with potassium carbonate or hydroxide; and when heated with carbon in the electric furnace, it forms calcium and aluminium carbides. E. T. Allen and H. F. Rogers prepared tetra- or penta-hydrated **strontium metaluminate,** $Sr(AlO_2)_2.4$ or $5H_2O$, as a gelatinous mass, not in a pure condition, by the action of cold strontia-water on aluminium; they also reported pentahydrated **barium metaluminate,** $Ba(AlO_2)_2.5H_2O$, to be formed as an amorphous powder by dissolving aluminium in a cold sat. soln. of baryta-water. The powder is easily decomposed by water and by carbon dioxide. H. St. C. Deville obtained a tetrahydrate by calcining a mixture of alumina with barium nitrate or carbonate, crystallizing the aq. extract, and recrystallizing from an alcoholic soln. E. Beckmann reported a hexahydrate which E. T. Allen and H. F. Rogers believe to be really the pentahydrate. J. A. Hedvall and N. von Zweigbergk thought a compound was formed when barium dioxide is heated with alumina.

The equilibrium diagram, Fig. 54, shows that a eutectic between $CaO.Al_2O_3-3CaO.5Al_2O_3$ occurs at 1580° with 67·5 per cent. of alumina; but **tricalcium decaluminate,** $3CaO.5Al_2O_3$, or $Ca_3Al_{10}O_{18}$, breaks down at about 1710°, and has no true m.p., although it is quite fused at 1725°. The crystals are rounded and belong either to the tetragonal or hexagonal system. The hardness is about 6·5. The birefringence is fairly strong, 0·032, and the refractive index for Na-light is $\omega=1{\cdot}617\pm0{\cdot}002$, and $\epsilon=1{\cdot}651\pm0{\cdot}002$. There is an unstable form of this compound with a sp. gr. 3·05 at 25°/25°. The relation between the two is monotropic, but even when rapidly quenched the unstable form inverts so readily that homogeneous crystals could not be obtained. The crystals are probably rhombic. The hardness is 5·5 to 6·0; the birefringence is about 0·013; the refractive index for Na-light is $\alpha=1{\cdot}662\pm0{\cdot}003$; $\beta=1{\cdot}671\pm0{\cdot}002$; and $\gamma=1{\cdot}674\pm0{\cdot}002$.

E. Candlot found that when calcium aluminate is treated with calcium chloride, **calcium chloroaluminate,** $3CaO.CaCl_2.Al_2O_3.10H_2O$, is formed. It is decomposed by contact with water, and is said to be momentarily formed during the action of a sat. soln. of calcium chloride on the anhydrous aluminate. According to H. Steinmetz, calcium chloroaluminate, $Ca(CaCl)AlO_3.5H_2O$, has a transition point at 35·8°, and its vol. then decreases. E. Candlot also obtained **calcium trioxytrisulphatodialuminate,** $3CaO.3CaSO_4.Al_2O_3.30H_2O$, by the action of calcium sulphate on the aluminate. This product is formed during the destructive action of sea-water on Portland cement. H. Kühl and H. Albert prepared **calcium trisulphatodialuminate,** $Ca_3O_2(AlO_2)_2.3CaSO_4$, by heating lime-water and a soln. of aluminium sulphate separately to various temp. between 0° and 100°, mixing the soln. in theoretical proportions, and maintaining the mixture at the same temp. for various periods up to 28 days. Below 40°, a precipitate consisting of minute needles of the salt was readily formed, but above 40°, a much smaller quantity of the salt (contaminated with a variable amount of calcium hydroxide, which is less soluble in hot water) was formed. This is supposed to furnish an explanation of the smaller expansion during the setting of mixtures of gypsum and portland cement above 40° than below that temp.

Barium aluminate has been recommended for the removal of calcium sulphate from boiler water on the commercial scale, it is found that a quantity of barium aluminate less than is required by the equation, $BaAl_2O_4+CaSO_4=BaSO_4+CaAl_2O_4$, is sufficient to precipitate the sulphate; the resulting liquid, however, is not entirely free from dissolved salts, and is always found to contain lime in soln. The subject has also been discussed by D. A. Peniakoff. A. Winkler sintered mixtures of alumina, potassium hydroxide, and lime, and the products have been called *potassium calcium aluminates*, although there is nothing to show that chemical individuals were formed.

The occurrence of the rare mineral *chrysoberyl* has been described in connection with beryllium. It is not the chrysoberyl of the ancients, for that is a variety of beryl. A. G. Werner[3] called it *krisoberil;* D. L. G. Karsten, D. G. J. Lenz, etc., called it *chrysoberyl;* and R. J. Haüy, *cymophane.* It was analyzed by M. H. Klaproth, J. A. Arfvedson, H. Seybert, G. Bergemann, A. von Awdéeff, A. Damour, etc. *Alexandrite* was described by N. G. Nordenskjöld. Chrysoberyl approximates in composition to **beryllium aluminate,** $Be(AlO_2)_2$. J. J. Ebelmen obtained it by melting a mixture of alumina, beryllia, calcium carbonate, and boric oxide for about 3 days at 1500°–1600°; P. Hautefeuille and A. Perrey heated a mixture of alumina, beryllia, potassium sulphate, and carbon to about 1100° for 4 hrs.; washed the cold product with acidulated water; removed the excess of beryllia with sulphuric acid, and the excess of carbon by oxidation. H. St. C. Deville and H. Caron heated a mixture of aluminium and beryllium fluorides in a carbon crucible arranged within a smaller carbon crucible, containing fused boric acid, embedded in the centre of the mixture. In a few hours, fine crystals of chrysoberyl were obtained. A. Lacroix obtained crystals of chrysoberyl by heating a beryllium salt with cryolite, and a silicate. If a chromium compound is present in the above syntheses, green crystals of alexandrite are obtained. The crystals are pleochroic, and they were found by G. Melczer to be pseudohexagonal, rhombic bipyramids with axial ratios $a:b:c$=0·4707 : 1 : 0·5823. L. Frischmann studied the twinning of the crystals. The crystals have a formal resemblance to those of olivine. J. J. Ebelmen gave 3·759 for the sp. gr., and the hardness is 8·5. A. Reis and L. Zimmermann discussed the hardness of chrysoberyl. L. F. Nilson and O. Pettersson gave 0·2004 for the sp. ht.; G. Melczer gave for the three refractive indices α, β, γ, 1·7440, 1·7431, and 1·7489 respectively for Li-light; 1·7443, 1·7470, and 1·7530 for Na-light; and 1·7474, 1·7503, and 1·7566 for Tl-light. The double refraction is positive, $\gamma-\alpha$=0·009.

According to H. Abich,[4] if equi-molar parts of magnesium and aluminium salts be mixed in aq. soln. with enough ammonium chloride to keep the magnesium in soln., the addition of ammonia precipitates the aluminium and nearly all the magnesium as hydroxides so as to form a kind of hydrated spinel; J. N. von Fuchs found the precipitate contained much ammonia. According to W. Heldt, some aluminium hydroxide is precipitated by adding magnesium hydroxide to a soln. of an aluminium salt; and magnesium sulphate gives a white gelatinous precipitate when added to a soln. of potassium aluminate, but calcined magnesia is not changed in an aq. soln. of potassium aluminate. J. Heyrovsky made a dil. soln. of magnesium aluminate and measured the f.p. J. J. Berzelius was unable to fuse a mixture of alumina and magnesia at the temp. of a smith's forge, but a calcined mixture of alumina with half per cent. of magnesia evolves much heat on being moistened with water, and when extracted with hydrochloric acid leaves a residue of **magnesium aluminate.** W. Heldt also made somewhat analogous observations with mixtures of alumina and magnesia. E. S. Shepherd, G. A. Rankin, and F. E. Wright found only one well-defined magnesium aluminate, $MgO.Al_2O_3$, or $Mg(AlO_2)_2$—artificial *spinel*—on the f.p. curve of mixtures of alumina and magnesia. The solid phases between 0 and 71·6 per cent. of alumina are magnesia and magnesium aluminate; the eutectic is at 1956°; and the solid phases between 71·6 and 100 per cent. of alumina are magnesium aluminate and alumina. J. J. Ebelmen obtained crystals of artificial spinel by heating a mixture of alumina, magnesia, calcium carbonate, and boric oxide—the crystals were coloured red if a small proportion of chromium be included; blue with cobalt; and black with ferric oxide—the cold, crushed mass was washed with hot conc. hydrochloric acid. W. Guertler used alkali metaborate as the solvent. E. Dufau heated a mixture of alumina and magnesia in an electric furnace, digested the cold mass with nitric acid, and separated the crystals of spinel with a heavy liquid—methylene iodide; no basic aluminate was obtained, but S. Meunier said that a *basic magnesium aluminate* can be obtained by melting magnesia, and cryolite with a large excess of alumina. Needle-like crystals, accompanied by corundum, occur in the cold mass. S. Meunier also made spinel by fusing a mixture of alumina, magnesia, cryolite, and aluminium chloride—without the latter, no spinel was formed; nor was it produced from a mixture of magnesia, alumina, and fluorspar, or from a mixture of magnesia and cryolite. He also prepared crystals of spinel by heating water, aluminium chloride, and magnesium in a sealed tube; A. Daubrée obtained spinel and corundum by passing the vapour of aluminium chloride over heated magnesia or by heating a mixture of lime with magnesium and aluminium chlorides. J. Morris made spinel by stirring an intimate mixture of carbon, and aluminium and magnesium chlorides into a paste with water; moulding the mass into briquettes; and heating the dried briquettes to redness in a stream of carbon dioxide for 50-500 hrs.

J. Morozewicz studied the conditions of formation of spinel in silicate magmas. W. Vernadsky observed spinel in the product obtained by fusing biotite; C. Doelter, clinochlore, and tourmaline; F. W. Clarke and E. A. Schneider, clinochlore, and xanthophyllite; W. Salomon, tourmaline, pyrope, and spessartite; F. Fouqué and A. Michel-Lévy, a mixture of nephelite and augite; C. Doelter and E. Hussak, a mixture of fayalite and sarcolite; M. Vucnik, a mixture of magnetite and anorthite; and B. Vukits, mixtures of elaeolite and augite or corundum. F. W. Clarke discussed the bearing of these observations on the occurrence of spinel in nature. P. Niggli studied the ternary system Al_2O_3—MgO—CaO.

Spinel, or *magnesia spinel*, occurs in colourless, holosymmetric crystals belonging to the cubic system. V. S. Deleano and E. Dittler measured the velocity of crystallization of spinel from the molten state. W. H. Bragg, L. Vegard, M. L. Huggins, P. F. Kerr, and S. Nishikawa found that the X-radiogram of magnesium aluminate corresponds with the cubic lattice of the diamond. W. Hermann's experiments on the action of oxidizing and reducing gases on heated spinel led him to the belief that the oxides of iron act as tinctorial agents in the blue and green spinels. It is found in nature coloured red with chromium oxide, and this variety has been regarded as a gem-stone, *precious spinel*, from very early times; to distinguish it from ruby, it is also called *ruby spinel* (deep red), or *balas ruby* (rose red); yellow or orange-red spinel is also called *rubicelle;* and violet spinel, *almadine.* Theophrastus in his *Περί λίθον* refers to the *ἀνθρακίνος*, so called because it is not injured by fire; the term is usually translated as carbuncle, and Pliny in his *Historia naturalis* (**37.** 25–29) refers to the *lychnis*, and to the *carbunculus*, so called because of its resemblance to fire. It is generally supposed that these terms refer to what are now known as spinel ruby, and corundum ruby. G. Agricola, C. Cappeller, and J. G. Wallerius also confused these minerals. J. B. L. Romé de l'Isle first clearly demonstrated the difference in the crystal forms of *rubis spinelle* and corundum ruby. Analyses have been published by J. J. Berzelius, T. Thomson, H. Abich, T. Scheerer, A. Erdmann, F. Pisani, H. Rose, A. Damour, A. Hilger, etc. The sp. gr. of ruby spinel is 3·548 and of blue spinel 3·542, according to J. J. Ebelmen, and 3·57 at 15°, according to E. Dufau – the sp. gr. of corundum is greater than this. Similarly the hardness of spinel ruby, 8·0, is smaller than that of corundum ruby, which is 8·8 to 9·0. A. Reis and L. Zimmermann gave 8·0 for the hardness of spinel. H. Fizeau found the coeff. of cubical expansion of Singalese ruby spinel to be 0·00001787 at 40°; and H. Kopp *gave 0·194 for the sp. ht. between 14° and 47°. The refractive index is high, but smaller than that of corundum ruby.* A. des Cloizeaux found for ruby spinel, *1·7121 for the Li-ray*, 1·7155 for the Na-ray, and 1·726 for the blue ray; and for a blue spinel G. Melczer obtained 1·7185–1·7200 with Na-light. O. Mügge observed radioactive haloes in some specimens of spinel. E. Dufau said that spinel is attacked with difficulty by chlorine, bromine, or iodine, but it is attacked, when warm, by fluorine; hydrofluoric and hydrochloric acids attack it with difficulty. H. Abich also found that hydrochloric acid has very little action on spinel, and he noted that sulphuric acid dissolves about one-third when the mixture is heated until the acid begins to evaporate; E. Dufau found that sulphuric acid has very little action on spinel, and A. Mitscherlich found that spinel dissolves in 2 hrs. in a mixture of sulphuric acid (3 : 1); or when boiled in a mixture of sulphuric and hydrofluoric acids. H. Abich said spinel is not at all attacked by nitric acid. E. Dufau found that spinel is not reduced by carbon in the electric furnace; it is not attacked by fused alkali carbonate, but it is readily decomposed by fused alkali hydroxide. F. H. Riddle described the manufacture of tubes and crucibles from spinel.

F. Hochsteller [5] found a hydrated magnesium aluminium hydroxide as a secondary mineral on serpentine at Snarum, Norway, and he called it *hydrotalcite* because it looked like talc; R. Hermann called a specimen from Shishimsk, Ural, *völknerite*—after Capt. Völkner; and a related mineral from Oxbow and Somerville, New York, was called by C. U. Shepard, *houghite*—after F. B. Hough. Analyses were made by R. Hermann, and S. W. Johnson. The composition approximates $Al(OH)_3.3Mg(OH)_2, 3H_2O$, or $Mg_3AlO.6H_2O$. The crystals are hexagonal; the sp. gr. is 2·04 to 2·09; and the hardness 2. W. W. Coblentz found the ultra-red transmission spectrum has bands at 7·5μ, 2μ, 3μ, and 4·7μ. The opacity is complete at 6μ. There is a band at 9·9μ in the ultra-red reflection spectrum.

In 1806, G. Ekeberg [6] analyzed the zinc analogue of spinel found in some schists at Fahlun (Sweden), and he named it *automolite*, from αὐτόμολος, a deserter, in allusion to the zinc occurring in an unexpected place; but C. E. von Moll objected to such an idea in nature, and called it *gahnite*, after J. G. Gahn, the discoverer. Analyses by G. Ekeberg, H. Abich, F. A. Genth, T. Thomson, A. Damour, F. von Kobell, F. Pisani, F. Mauro, J. D. Dana, H. Hedström, etc., correspond with the formula for **zinc aluminate**, $Zn(AlO_2)_2$. More or less ferrous iron may replace the zinc; and in the *dysluite* of W. H. Keating, and in the *kreittonnite* of F. von Kobell, some ferric iron replaces the alumina, and some manganous oxide the magnesia—possibly isomorphous mixtures or solid soln.; *franklinite*, $(Zn,Mn)Fe_2O_4$, and *magnetite*, $Fe(FeO_2)$, and *chromite*, $Fe(CrO_2)_2$, may be regarded as advanced or extreme stages in the substitution, or extreme members of the series of mixed crystals. J. J. Berzelius found that aluminium hydroxide abstracts zinc oxide from the aq. soln. of ammoniacal zinc oxide; and zinc aluminate is precipitated from the same soln. by adding a sat. soln. of potassium aluminate. T. Sander found a precipitate is obtained on mixing soln. of potassium aluminate and zincate. J. J. Ebelmen, and J. R. Mourelo synthesized gahnite by heating a mixture of zinc oxide, alumina, and boric oxide; S. Meunier, by heating to bright redness a mixture of alumima, zinc oxide, cryolite, and aluminium chloride. A. Daubrée, by passing the vapours of aluminium and zinc chlorides over red-hot lime; H. St. C. Deville and H. Caron, by vaporizing a mixture of zinc and aluminium fluorides in the presence of boric oxide. A. Stelzner found gahnite in the walls of a zinc muffle at Freiberg, and G. J. Brush at New Jersey. W. Biltz regarded the violet colour of zinc aluminate as a result of the union of compounds of elements in different states of oxidation. E. V. Shannon described a blue cobaltiferous gahnite from Maryland. The crystals are cubic and are isomorphous with spinel. W. H. Bragg studied the X-radiogram; and M. L. Huggins, the electronic structure. According to J. J. Ebelmen, the sp. gr. is 4·58, and the crystals are harder than quartz. H. Hedström gave 4·39 for the sp. gr., and W. Ortloff 7·5 to 8 for the hardness. A. Reis and L. Zimmermann gave 8·0 for the hardness of zinc spinel. H. Rosenbuch gave 1·765 for the refractive index. According to J. J. Berzelius, gahnite bakes together when heated with sodium carbonate but is not dissolved; it is slightly soluble in fused borax or microcosmic salt; but fuses to a clear glass with a mixture of borax and sodium carbonate. Gahnite is virtually insoluble in acids and alkali-lye. J. J. Ebelmen failed to prepare *cadmium aluminate* by heating a mixture of alumina, cadmium oxide, and boric oxide, for aluminium borate was formed, while the cadmium volatilized.

J. Smithson[7] described *plomb-gomme* as a native hydrated *lead aluminate*—*vide* lead phosphates. E. J. Kohlmeyer found it difficult to melt lead oxide and alumina because at the necessary temp. lead oxide rapidly volatilizes. A. Stavenhagen and E. Schuchardt found that the product has a blue cathodoluminescence. L. F. Hawley made **thallous aluminate,** $Tl_4Al_2O_5.7H_2O$, by the dissolving aluminium in a cold soln. of thallous hydroxide. It is insoluble in absolute alcohol, and readily soluble in dil. acids and alkali hydroxides. It is slowly hydrolyzed by water, and the aq. soln. is decomposed by carbon dioxide, forming thallous carbonate and aluminium hydroxide.

J. J. Ebelmen[8] prepared crystals of **manganous aluminate,** $Mn(AlO_2)_2$, or *manganese spinel,* belonging to the cubic system by heating a mixture of alumina, manganous oxide, and boric oxide for three days to 1500°–1600°; and E. Dufau, by heating a mixture of aluminium and manganic oxide in an electric furnace. The mass was treated with boiling hydrochloric acid. J. A. Krenner found crystals of manganese spinel in some blast furnace slag; *dysluite* may be regarded as manganese spinel in which much of the alumina has been displaced by ferric oxide—*vide supra.* According to E. Dufau, the sp. gr. of manganese spinel at 20° was 4·12; the crystals scratch quartz. The salt is easily oxidized when heated in air, and rapidly attacked by chlorine; at a red heat with fluorine it becomes incandescent. Sulphur, bromine, and iodine react at the softening temp. of glass. It is insoluble in hydrochloric acid, is attacked by hydrofluoric and nitric acids, and readily dissolved by sulphuric acid. Fused potassium chlorate, nitrate, hydroxide, and carbonate easily decompose manganese spinel.

The ferrous analogue of spinel, **ferrous aluminate,** $Fe(AlO_2)_2$, *i.e. iron spinel,* is represented by the mineral *hercynite,* discovered at Ronsberg by F. X. M. Zippe,[9] and named from the Latin term for the Bohemian Forest—*silva hercynia.* The mineral was analyzed by B. Quadrat. It occurs as black magnetic specks in the Saxon granulites. It also occurs massive and granular; it is black in colour; its sp. gr. is 3·91–3·95; and its hardness is 7·5–8. J. J. Ebelmen obtained a mass covered with brown intersecting needles by heating a mixture of alumina, ferric oxide, and boric oxide for three days at 1500°–1600°. The minerals spinel ruby, hercynite, gahnite, magnetite, magnesioferrite, $Mg(FeO_2)_2$, jacobsite, $Mn(FeO_2)_2$, franklinite, $(Zn, Mn)(FeO_2)_2$, and chromite, $Fe(CrO_2)_2$, form a natural group of cubic minerals, $M''R_2'''O_4$, in which there are many intermediate forms. The basic element may be magnesium, ferrous iron, zinc, or manganese; and where R''' may be tervalent aluminium, iron, manganese, or chromium.

In illustration, the *ceylanite* of J. C. Delamétherie, the *zeylanite* of D. L. G. Karsten, the *pleonaste* of R. J. Haüy, the *ceylonite* of C. F. Rammelsberg, and the *candite* of Comte de Bournon is an *iron-magnesia spinel,* varying in colour from dark green, brown, or black, and have a composition corresponding with isomorphous mixtures represented by

$(Mg, Fe)O.(Al, Fe)_2O_3$. These minerals have been reported in garnetiferous gneisses, and metamorphic rocks. The so-called *chlorospinel* occurs in grass-green or greyish-green regular octahedrons, of sp. gr. 3·593, and is considered by G. Rose to be a magnesia spinel with part of the alumina replaced by ferric oxide. It also contains about 0·27 per cent. of copper oxide. The mineral *picotite* is a chrome-ceylonite and was first described by Picot de la Peyrouse and named by J. C. Delamétherie *lherzolite* from Lherz, where the mineral was first obtained as heavy black grains in olivine rocks; it is also found in serpentine. J. F. W. Charpentier named the mineral picotite after its discoverer. It contains about 7 per cent. of chromic oxide as well as magnesia, alumina, and ferrous and ferric oxides—$(Mg, Fe)O(Al, Fe, Cr)_2O_3$. The *högbomite* of A. Gavelin approximates $MgO(Al_2O_3.Fe_2O_3.TiO_2)_2$. It occurs in Swedish Lapland. The sp. gr. is 3 81; the hardness, 6½; the axial ratio $a : c$ of the rhombohedral crystals is 1 : 1·55; and the indices of refraction, $\omega = 1·853$, and $\epsilon = 1·803$.

About the end of the eighteenth century, J. G. Gahn[10] discovered the fine blue colour which is produced when alumina, or a substance containing alumina as free as possible from iron, is ignited with a salt of cobalt. It was mentioned by C. F. Wenzel. J. J. Berzelius described it in 1812. The colour is improved if phosphates or arsenates are present, and the product obtained by calcining a mixture of alumina with cobalt phosphate or arsenate was described by L. J. Thénard; and the colour produced by calcining alumina with cobalt oxide or cobalt salts came to be called *Thénard's blue*, or *cobalt-ultramarine*, *Leyden blue*, or *Leithner's blue*. According to P. Louyet, a mixture of cobalt and aluminium hydroxides does not assume the true blue colour at a temp. below the m.p. of glass, a red heat renders the mixture black or grey; but if cobalt phosphate or arsenate is used, the blue is developed at a red heat. J. J. Ebelmen did not succeed in making crystals of **cobalt aluminate,** $CoO.Al_2O_3$, analogous with the spinels by the process he employed for other spinels—*vide supra*. W. Stein, and S. Burgstaller regarded Thénard's blue as a solid soln. of cobalt oxide in alumina. J. A. Hedvall heated the mixture of the two oxides with potassium chloride and obtained crystals of cobalt aluminate which he regards as a true chemical compound—sp. gr. 4·37 at 18°. He also obtained a green aluminate, $4CoO.3Al_2O_3$. M. Rüger also prepared cobalt aluminate; and he showed that the green intermediate product obtained by heating the mixture of cobalt oxide and alumina at 900° is a solid soln. of aluminate.

§ 13. Aluminium Fluoride

The mineral *fluellite*, $AlF_3.H_2O$, was discovered by A. Levy[1] in 1824. It is a rare mineral—colourless or white, with or without a tinge of yellow—found at Stenna-gwyn (Cornwall) in minute crystals along with wavellite and uranite on quartz. In 1824, J. J. Berzelius[2] dissolved alumina in hydrofluoric acid, and on evaporation, obtained a syrup which formed a hydrated gum-like mass dissolving slowly in cold water and rapidly in hot. J. J. Berzelius noted that when heated, the hydrated compound loses hydrogen fluoride and forms a basic aluminium fluoride; indeed, L. Schuch converted aluminium fluoride into alumina and hydrogen fluoride by heating it in a stream of water vapour, $2AlF_3+3H_2O$

$\rightleftharpoons Al_2O_3+6HF$. C. Brunner found that when alumina is heated to redness, it absorbs the vapour of hydrogen fluoride, and gives off water, but quantitative results were not obtained. According to H. St. C. Deville, if either product be heated in a carbon tube in a stream of hydrogen, at a white heat, most of the aluminium fluoride sublimes and forms rhombohedral crystals. According to P. Hautefeuille, if alumina be heated to a high temp. in a stream of moist hydrogen fluoride crystals of corundum, Al_2O_3, and of aluminium fluoride are produced.

H. St. C. Deville obtained aluminium fluoride by distilling a mixture of aluminium sulphate and cryolite in a stream of hydrogen; and also by heating a mixture of fluorspar and alumina in a stream of hydrogen chloride; M. Strakosch and C. O. Weber heated a mixture of sodium fluoride with aluminium sulphate and extracted the aluminium fluoride with water; A. Cossa obtained aluminium fluoride by heating a mixture of aluminium sulphate and magnesium fluoride H. St. C. Deville prepared aluminium fluoride by decomposing silicon tetrafluoride with alumina, and he removed the silicon by means of a mixture of hydrofluoric and nitric acids; he also made aluminium fluoride by heating hydrofluosilicic acid with alumina or china clay; and L. Troost and P. Hautefeuille, by heating alumina in a stream of silicon fluoride. H. Moissan obtained aluminium fluoride by the action of fluorine on aluminium; in the cold the metal is superficially attacked, but when heated the reaction is complete; C. Poulenc also prepared the same compound by the action of hydrogen fluoride on aluminium at 1000°; W. K. van Haagen and E. F. Smith used alumina.

According to H. St. C. Deville and A. de Schulten, anhydrous aluminium fluoride crystallizes in colourless, transparent, obtuse rhombohedra, but, according to C. Poulenc, the crystals are probably triclinic. C. H. D. Bödeker gave the sp. gr. as 3·065 to 3·13 at 12°. W. Biltz gave 27·1 for the mol. vol. P. P. Fedoteeff and W. Iljinsky found the m.p., or rather the freezing temp., of aluminium fluoride to be 1000°; N. A. Puschin and A. V. Baskoff give 1040°. E. Baud's value for the heat of formation of aluminium fluoride from its elements is 499 Cals., which is the greatest of all the aluminium-halogen compounds. O. Pettersson gives the heat of formation $2\{Al(OH)_3, 3HF_{aq.}\}=3\times 23{\cdot}415$ Cals.; E. Baud gives the heat of soln. of $AlF_3.3{\cdot}5H_2O$ at 15° as $-3{\cdot}33$ Cals.; of $2AlF_3.H_2O$ at 15° as 51·15 Cals.; the heat of formation $2AlF_{3solid}+H_2O_{gas}=2AlF_3.H_2O_{solid}+33{\cdot}33$ Cals., and with liquid water, 23·68 Cals. Similarly, $2AlF_{3solid}+7H_2O_{liquid}=2AlF_3.7H_2O_{soluble}+64{\cdot}95$ Cals., and for insoluble $2AlF_3.7H_2O$, 65·95 Cals. In spite of a little ionization, A. Speransky found the mol. wt. of aluminium fluoride in aq. soln. to be greater than corresponds with the formula AlF_3. H. St. C. Deville reported that anhydrous aluminium fluoride is inert chemically, for it is not attacked by water or acids; it is slightly attacked by boiling sulphuric acid, but is not changed by boiling potash-lye; it is decomposed by heating it with calcium oxide at a white heat, and with fused sodium carbonate when a part of the fluorine is volatilized as sodium fluoride. L. Schuch said that the crystals are decomposed completely into alumina and hydrogen fluoride when heated in a current of steam; E. Baud found that aluminium fluoride volatilizes with partial decomposition when heated in a stream of hydrogen; and that the volatilization of aluminium fluoride at a red heat is attended by much decomposition. E. Frémy and C. Feil obtained aluminium borate by fusing aluminium fluoride with boric oxide; A. von Bartal observed no change when carbonyl chloride is passed over cold or heated aluminium fluoride. W. Hampe heated cryolite with aluminium and obtained what he regarded either as **aluminium subfluoride,** AlF_2, or a double salt of this subfluoride with sodium fluoride. W. Diehl contested the validity of W. Hampe's conclusion, but W. Hampe further claimed to have formed the same compound by the electrolysis of cryolite.

A. Mazzucchelli says that the contradictory observations which have been reported on the various hydrates of aluminium fluoride are due to complications traceable to metastability and supersaturation; to the slowness with which the solids and soln. attain a state of equilibrium; and to the existence of hydrates with the same composition but with different solubilities and degrees of resistance to the action of heat. A. Mazzucchelli obtained silky filaments of **monohydrated aluminium fluoride,** $AlF_3.H_2O$, by evaporating a dil. aq. soln. or a small quantity of a conc. neutral soln. of the salt to dryness, on a water-bath. This product is sparingly soluble in water, by which it is transformed into $AlF_3.3H_2O$. The mineral *fluellite, $AlF_3.H_2O$, crystallizes in bipyramids belonging to the rhombic system, and having the axial ratios $a:b:c=0{\cdot}770:1:1{\cdot}8776$; hardness 3; sp. gr. 2·17; and refractive index 1·47. A. Mazzucchelli states that a soln. of aluminium fluoride is most conveniently prepared by suspending 42 grms. of basic aluminium acetate and 54 grms. of alumina in about 100 c.c. of water and 66 grms. of 40 per cent. hydrofluoric acid. Soln. occurs either at once or after boiling for a short time. The soln. gradually deposits a gelatinous or colloidal hydrate of aluminium fluoride approximately **trihydrated aluminium fluoride,** $AlF_3.3H_2O$. The same dil. soln. gradually deposit a crystalline crust of a similar composition, $AlF_3.3H_2O$. L. H. Milligan said the product is granular if the soln. contains free acid eq. in amount to the aluminium.

A. Mazzucchelli also found that if 75 c.c. of water be used in place of 100 c.c. in the preceding method of preparation, the liquid becomes very much heated, and, on cooling, deposits crystals of **hemiheptadecahydrated aluminium fluoride,** $AlF_3.8\frac{1}{2}H_2O$, which can also be obtained as a felted mass of short needles by cooling below 0°, a more dil. soln. of aluminium fluoride. A sat. aq. soln. of hemiheptadecahydrated aluminium fluoride at 11° contains 3·85 grms. of AlF_3, and at $-0{\cdot}2°$, 1·20 grms. The crystals effloresce rapidly and become opaque, even in a sealed tube; the soluble metastable hydrate passes into the trihydrated fluoride, which is the most stable hydrate under ordinary conditions. According to E. Baud, and A. Mazzucchelli, when two volumes of alcohol are added to one volume of a neutral soln. of alumina in hydrofluoric acid, a crystalline precipitate of **hemiheptahydrated aluminium fluoride,** $AlF_3.3\frac{1}{2}H_2O$, which is readily soluble in water, is obtained. The soln. is acid to litmus, and neutral to methyl orange. Another form of hemiheptahydrated aluminium fluoride almost insoluble in water is made by evaporating at 100° a soln. of alumina in aq. hydrofluoric acid. The hemiheptahydrated fluoride remains unchanged in vacuo or over sulphuric acid; it loses 2 mols of water at 100°; half a mol between 150° and 170°; and another half mol. between 210° and 250°. The residual hemihydrated *aluminium fluoride,* $AlF_3.\frac{1}{2}H_2O$, does not decompose at a bright red heat. The hemiheptahydrated fluoride gradually changes to the trihydrated fluoride in contact with water. The heat of soln. of the soluble form of $AlF_3.3\frac{1}{2}H_2O$ is 1 Cal. less than that of the insoluble form, and this corresponds with the heat evolved in the transformation of the soluble into the insoluble modification. A. von Bartal found that carbonyl chloride does not react with aluminium fluoride even at a red heat. G. L. Clark found aluminium fluoride adsorbs ammonia very slowly, forming **aluminium amminochloride,** $AlF_3.NH_3$.

§ 14. The Fluoaluminates

Aluminium fluoride forms a number of double compounds with other metal fluorides. The majority of compounds with the alkali fluorides seem to be salts of the complex **hydrofluoaluminic acid,** $3HF.AlF_3$, or H_3AlF_6. This acid has not been isolated, but H. St. C. Deville[1] reported two acid compounds of aluminium fluoride, namely, (i) $2HF.3AlF_3.5H_2O$, prepared by half saturating hydrofluoric acid with aluminium hydroxide, and adding alcohol. The oily liquid which separates soon crystallizes; and (ii) $HF.2AlF_3.5H_2O$, prepared by evaporating the preceding soln., washing the crystalline residue with boiling water, and drying it in air.

By pouring an excess of a soln. of ammonium fluoride into one of aluminium fluoride, E. Baud obtained a gelatinous precipitate which soon settles. It is supposed to be **ammonium pentafluoaluminate,** $2NH_4F.AlF_3.1\frac{1}{2}H_2O$, or $(NH_4)_2AlF_5.1\frac{1}{2}H_2O$. The heat of soln. is −17·09 Cals.; and 100 parts of water dissolve one part of the salt. J. J. Berzelius boiled aluminium hydroxide in an aq. soln. of ammonium fluoride and found part of the ammonia is expelled and a transparent jelly which dries to a white powder is formed. H. von Helmolt washed the gelatinous precipitate with dil. alcohol, and found it to be the ammonium analogue of cryolite—**ammonium hexafluoaluminate,** $(NH_4)_3AlF_6$, or $3NH_4F.AlF_3$—with conc. soln. octahedral crystals, belonging to the cubic system, are precipitated. The salt is feebly soluble in water, and, according to H. von Helmolt, ammonia does not precipitate alumina from the soln.; while, according to J. J. Berzelius, the salt is not soluble in water containing ammonia or ammonium fluoride, and either of these compounds precipitates the salt from its aq. soln. When heated, the salt gives off ammonia, and then ammonium hydrogen fluoride, leaving a residue of aluminium oxyfluoride. J. Petersen prepared a similar salt.

J. J. Berzelius[2] obtained lithium fluoaluminate as a white powder, insoluble in water, by treating lithium hydrofluoride with aluminium hydroxide. N. A. Puschin and A. V. Baskoff found the m.p. curve of lithium fluoride is of the type shown in Fig. 54. The curve falls from 870° to a eutectic at 706° with 14·5 molar per cent. of aluminium fluoride, and then rises to a maximum over 783°—say 800°—when the mixture corresponds with the lithium analogue of cryolite, **lithium hexafluoaluminate,** $3LiF.AlF_3$, or Li_3AlF_6; the temp. then falls to the eutectic 691° with 37 mol per cent. of aluminium fluoride. The curve was not further explored. The mineral *cryolithionite* is a double **sodium lithium fluoaluminate,** $Na_3Li_3Al_2F_{12}$, or $2AlF_3.3NaF.3LiF$. It occurs as cubic crystals at Ivigtut (Greenland) and in the Ilmen Mountains (Urals). According to N. V. Ussing, the hardness is 2–3; sp. gr., 2·774–2·778; index of refraction for the Li-line, 1·3382; for the Na-line, 1·3395; and for the Tl-line, 1·3408. The crystals decrepitate when heated to redness; they soften at 700°, and, according to N. V. Ussing, melt at 710°. The solid is rather more soluble in water than cryolite—100 c.c. of water at 18° dissolve 0·074 grm. of cryolithionite. The aq. soln., on evaporation, gives small cubic crystals, which are decomposed by warm sulphuric acid.

The minerals containing sodium and aluminium fluorides are: *cryolite*, which has a composition corresponding with $AlF_3.3NaF$; *cryolithionite*, with $2AlF_3.3NaF.3LiF$; *chiolite*, with $3AlF_3.5NaF$, or with $AlF_3.1\frac{2}{3}NaF$; and *ralstonite*, with $3Al(F, OH)_3.(Na_2, Mg)F_2.2H_2O$; *pachnolite* and *thomsenolite*, which are dimorphic forms with the composition $AlF_3.CaF_2.NaF.H_2O$. According to G. F. Schumacher,[3] a sample of cryolite was brought from Greenland to Copenhagen in 1795, but was thought to be barytes until P. C. Abildgaard found it to contain fluorine and aluminium; the residue was found by M. H. Klaproth, and L. N. Vauquelin in 1800, to be sodium; and R. J. Haüy described it, in 1801, as *fluate d'alumine et de soude des chimistes.* The resemblance of the mineral to snow, and its still greater likeness, when wet, to ice, suggested to P. C. Abildgaard the name *kryolith, kryolite,* or **cryolite**—*κρύος*, frost; and λίθος, stone. E. F. Glocker called it *Eisstein*—ice-stone. The mineral was later described by J. B. d'Andrada and D. L. G. Karsten. In 1811, K. L. Giesecke discovered a large deposit of cryolite at the place now known as Ivigtut in Frederikshaab, in the south-west of Greenland. This is virtually the only deposit of commercial importance known at the present time; although comparatively small deposits have been found at Miask (Ural Mountains); in the granite at the north-east base of St. Peter's dome, Pike's Peak, Colorado; Yellowstone National Park, Wyoming; and at Aragonien Huesca, Spain. The fluorine compounds, says F. W. Clarke, are rarely found in eruptive rocks; they are especially characteristic of deep-seated or plutonic rocks, where the gaseous exhalations have been retained under press., and are commonly regarded as of pneumatolytic origin. F. Johnstrup says that the bed of cryolite is a concretionary secretion in eruptive granite; and R. Baldauf supposes it to have been formed by the action of fluoriferous gases upon the original granite magma.

The minerals—quartz, siderite, galenite, sphalerite, pyrite, chalcopyrite, and wolframite—irregularly scattered through the mass of cryolite, are separated by hand-sorting. There are also mineral impurities—pachnolite, thomsenolite, arksuktite, gearksuktite, ralstonite, prosopite, ivigtite, and hagemannite—all comparatively rare, or found only in association with cryolite; these are separated from cryolite in the process of manufacture since they suffer no change under the chemical treatment by which cryolite is decomposed. The cryolite mines were opened by D. Schmidt in 1857, and the Danish Government, which owns the mines, claims one-fifth of every cubic fathom (13·6 tons of 2240 lbs.) of cryolite mined and shipped from Greenland. The cryolite is mined mainly in summer; it is then sorted into first and second grades.

Cryolite was formerly the chief source of aluminium, but was superseded by bauxite. H. Rose, and A. Dick obtained aluminium from cryolite in 1855 by fusing the mineral packed with alternate layers of sodium in a magnesia-lined crucible. Cryolite is still used in the production of the metal, but not as a source of supply, for it is used as a solvent for the alumina since, when fused, it dissolves over 21 per cent. of alumina. During electrolysis the alumina is decomposed. A small amount of soda and alumina is manufactured from cryolite by J. Thomsen's process. Cryolite is also used as an opacifying agent in the manufacture of opaque glass—*e.g. cryolite glass* or *hot-cast porcelain*—and enamels.

J. J. Berzelius[4] prepared **sodium fluoaluminate** by adding aluminium hydroxide to an aq. soln. of sodium hydrofluoride until the acidity was neutralized; if sodium fluoride alone is used, half the sodium is liberated as hydroxide and remains in soln. as sodium aluminate; L. Schuch, and O. T. Christensen showed the reaction is probably that symbolized: $6NaF+2Al_2O_3 \rightleftharpoons Na_3AlF_6+3NaAlO_2$. E. Baud also mixed a dil. soln. of sodium fluoride with the correct quantity of aluminium fluoride. H. St. C. Deville neutralized a mixture of aluminium hydroxide and sodium carbonate with hydrofluoric acid. The soln. in either case were evaporated to a gelatinous mass which dries to a white powder. The Société Anon. d'Alum precipitates the double salt by adding sodium chloride to a soln. of aluminium hydroxide in an excess of hydrofluoric acid. L. Schuch mixed cryolite with soda-lye of sp. gr. 1·26, whereby a soln. of sodium aluminate was formed: $Na_3AlF_6+4NaOH=6NaF+NaAlO_2+2H_2O$; if carbon dioxide be passed through the boiling soln. pulverulent sodium aluminate is precipitated and the admixed aluminium hydroxide can be removed by treatment with acetic acid. H. St. C. Deville prepared sodium fluoaluminate by melting aluminium chloride or sodium chloroaluminate with sodium fluoride; and by treating the soln. of aluminium fluoride, obtained by the action of hydrofluosilicic acid on china clay, with sodium fluoride. H. Howard also reported processes for making what was called artificial cryolite.

H. St. C. Deville prepared sodium fluoaluminate by melting sodium fluoride with aluminium fluoride; this binary system has been studied by P. P. Fedotieff and W. P. Ilinsky, and N. A. Puschin and A. V. Baskoff; they found the only compounds of the binary mixture were $3NaF.AlF_3$, and $5NaF.3AlF_3$, the latter being analogous with the mineral *chiolite*. The fusion curve is indicated in Fig. 57. There are two eutectics, the compound $5NaF.3AlF_3$ breaks up at 735° into $3NaF.AlF_3$ and AlF_3. The cooling curve of solid sodium hexafluoaluminate shows, at 600°, a break which is interpreted to mean that there is a polymorphic transformation into the variety stable at ordinary temp. It will be observed that the fall of the curve shows that the addition of sodium fluoride to cryolite reduces the fusion temp. from 1000° down to 735°.

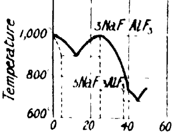

FIG. 57.—Freezing Curves of Mixtures of Aluminium and Sodium Fluorides.

Sodium fluoaluminate prepared by the wet processes is a white powder resembling magnesia, but cryolite may occur in monoclinic prisms with axial ratios, according to J. A. Krenner,[5] $a : b : c = 0.96625 : 1 : 1.38824$, and $\beta = 89° 49'$; usually, however, it occurs massive. According to R. Nacken, the monoclinic crystals of cryolite pass into a cubic modification at about 550°–570°; and F. Cornu suggests that the cubic modification $(3NaF.AlF_3)_2$ is isomorphous with cryolithionite, $Li_3Na_3Al_2F_{12}$—*vide infra*. The colour varies from snow-white to yellowish or reddish-white; it breaks in three directions with rectangular cleavages; it is brittle with an uneven fracture; and is translucent with a vitreous lustre. The hardness is between 2 and 3; and its sp. gr. between 2·95 and 3·0. The fusibility of cryolite was early noted by J. J. Berzelius—it can be fused in the flame of a candle; its m.p. is a little below 1000°—N. V. Ussing gives 920°. W. Moldenhauer gives 985°; F. R. Pyne and Y. S. Hardcastle give 1000°; N. A. Puschin and A. V. Baskoff give 1020°. The powder sticks together when heated to 870°. J. J. Berzelius noted that cryolite fuses at a red heat, and, on cooling, forms an opaque glass; O. Mügge found that on cooling molten cryolite, a crust with a skin of crystal skeletons resembling snow stars is formed. This crust is isotropic, and O. Mügge therefore argues that the crystals are either cubic or hexagonal—probably the latter. J. Smithson found that when the fused mineral is exposed to the air for a long time, it loses its ready fusibility owing to the loss of hydrogen fluoride. R. Nacken also found that it cannot be heated in an open vessel at atm. press., without the sublimation of some aluminium fluoride; and O. Mügge noticed that when small fragments are heated they first become turbid, then clarify, and afterwards evolve vapours of sodium fluoride. P. Oeberg's value for the sp. ht. is 0·2522, and A. Joly's value, 0·2548. The crystals have a feeble and positive double refraction; J. A. Krenner's value for the index of refraction is 1·364 for sodium light; M. Websky's value for candle-light is 1·3343; and O. B. Böggild's value is 1·3390. T. Liebisch and H. Rubens studied the optical properties of crystals of cryolite in the infra-red spectrum. E. Newbery and H. Lupton noted that the colour of the salt suffered no change on exposure to radium-rays; and there was a slight thermoluminescence. K. Arndt and H. Probst studied the electrolysis of cryolite—*vide* aluminium metal. When the crystals are gradually warmed, D. Hahn found that they show a yellowish luminescence, which, with rather stronger heating, does not become paler, but with still stronger heating is lost. F. Kreutz found cryolite to be blackened by a prolonged exposure to the cathode rays, and decolorized by exposure to the air for a few minutes; he recalls J. W. Taylor's and F. Kreutz's statements that cryolite from the deepest layers in the mines is black, and only when exposed to the air does the surface become white. E. Wartmann, and F. Beijerinck say cryolite is a non-conductor of electricity, but H. St. C. Deville showed that it becomes a conductor and melts at a lower temp. if other alkali halides be present.

F. Johnstrup[6] says cryolite is easily attacked by atm. moisture. At 12°, 100 parts of water dissolve 0·0366 part of cryolite, and the solubility is augmented if carbon dioxide be present. F. Lauterborn proposed the decomposition of cryolite by boiling with water in order to extract sodium fluoride. L. Pfaundler observed no chemical action when bromine is passed over molten cryolite. F. Wöhler found that when heated with ammonium chloride, some ammonium fluoride is volatilized, part of the sodium fluoride is converted into the chloride, and the product is more fusible than cryolite alone. J. J. Berzelius says that hydrofluoric acid is evolved when cryolite is heated with conc. sulphuric acid; and F. Wöhler found that both sodium and aluminium sulphates are formed, and a process by J. F. Persoz for the extraction of soda from cryolite was based on this reaction. F. Leydolt and H. Baumhauer have studied the etching figures of cryolite with sulphuric acid. F. Wöhler detected no reaction when cryolite is boiled with a soln. of aluminium sulphate. N. N. Beketoff observed that aluminium metal is formed when cryolite is heated with magnesium; H. St. C. Deville observed a similar result when cryolite is heated with sodium. C. Tissier observed no reaction when cryolite is boiled with a soln. of magnesium hydroxide, but L. Schuch observed that boiling soln. of sodium hydroxide form sodium fluoride and sodium aluminate. J. Thomsen's process for extracting alumina and soda (*q.v.*) from cryolite is based on the decomposition which occurs when cryolite is heated with calcium carbonate or oxide, and subsequently leached with water. R. von Wagner proposed baryta in place of lime, but the substitute was too costly. F. G. Spilsbury patented a process in which cryolite was decomposed by heating it with milk of lime, and C. Tissier tried it, but obtained only a 33 per cent. yield. D. Sauerwein showed that at least six mols of lime are needed for one of cryolite if the decomposition is to be complete: $2Na_3AlF_6+7Ca(OH)_2=6NaOH+Ca(AlO_2)_2+6CaF_2+4H_2O$. H. Bauer proposed melting cryolite with 2½ times its weight of calcium sulphate: $2Na_3AlF_6+3CaSO_4=3Na_2SO_4+3CaF_2+2AlF_3$, and removing the soluble salts by leaching with water; he also proposed boiling cryolite with a mixture of its own weight of calcium carbonate, 30-40 parts of water, and one per cent. of sodium hydroxide. L. Schuch also decomposed cryolite by boiling it with sodium silicate whereby insoluble aluminium silicate and soluble sodium fluoride are formed—the decomposition is incomplete. J. Lemberg observed that with a soln. of calcium chloride at 100°, part of the sodium in powdered cryolite is replaced by calcium and pachnolite is formed. C. Nöllner obtained similar results with soln. of calcium, barium, or magnesium chloride or strontium nitrate. J. Lemberg also studied the action of lead nitrate soln. on cryolite. E. Paterno and U. Alvisi noted the slow evolution of hydrofluoric acid when powdered cryolite is heated with a soln. of oxalic acid.

N. V. Ussing found rhombic dodecahedra belonging to the cubic system in the cryolite at Ivigtut, Greenland. The composition corresponds with **sodium lithium fluoaluminate,** $Li_3Na_3Al_2F_{12}$, and was named *cryolithionite*. The crystals contain liquid inclusions and also cryolite. The cleavage is parallel to the faces of the rhombic dodecahedron; the sp. gr. is 2·77; the hardness 2½ to 3; and the refractive index for Na-light, 1·3395. The m.p. is 710°, and when the magma cools, rectangular arborescent crystals are formed. A litre of water at 18° dissolves about 0·8 part of the mineral. The mineral is said to be crystallographically related more to garnet, $Ca_3Si_3Al_2O_{12}$, than to cryolite. F. Cornu[7] said that the cubic form of cryolite is probably isomorphous with this mineral. Cryolithionite contains a higher proportion of lithium than any known mineral. W. Cross and W. F. Hillebrand found a native form of cryolite at El Paso (Colorado, U.S.A.) with about two-thirds of the sodium replaced by potassium, and the mineral was called *elpasolite*. The crystals are isotropic—cubes or octahedra.

Two compounds of aluminium and potassium fluorides have been described, and also some hydrated forms. J. J. Berzelius precipitated **potassium pentafluoaluminate,** K_2AlF_5, or $2KF.AlF_3$, by stirring an aq. soln. of aluminium fluoride with insufficient potassium fluoride for complete saturation—if a slight excess of potassium fluoride be employed, he noted that **potassium hexafluoaluminate,** $AlF_3.3KF$, or K_3AlF_6, is formed; and that a permanent precipitate of K_3AlF_6 is formed in a soln. of alum, only when an excess of potassium fluoride is added. According to J. J. Berzelius, also, potassium pentafluoaluminate is formed, by digesting aluminium hydroxide with aq. potassium hydrogen fluoride—the first portions of the aluminium hydroxide dissolve, but when more of the aluminium hydroxide is added, the salt K_2AlF_5 separates out: $6KHF_2+Al_2O_3=2K_2AlF_5+3H_2O+2KF$; while if the gelatinous precipitate be boiled with the supernatant liquid, potassium hexafluoaluminate, K_3AlF_6—the potassium analogue of cryolite—is formed, and if the boiling be continued still further the salt is hydrolyzed and a basic salt is formed. L. Schuch obtained gelatinous aluminium hexafluoroaluminate by boiling aluminium hydroxide with potassium fluoride. E. Baud used very dil. aq. soln. of the component salts, and obtained a gelatinous precipitate whose composition corresponded with $K_3AlF_6.3\frac{1}{2}H_2O$. H. St. C. Deville also prepared the last-named compound by fusing aluminium chloride with an excess of potassium fluoride; A. Duboin, by fusing alumina with potassium fluosilicate and an excess of potassium fluoride; and N. A. Puschin and A. V. Baskoff, by fusing together mol. proportions of the component salts. The curve resembles that shown in Fig. 53; there is a eutectic at 837° when 7·5 mol per cent. of aluminium fluoride is present, and there is also another eutectic at 568° with about 40 mol per cent. of aluminium fluoride is present; between the two eutectic points the curve rises to a maximum at 1030° when the composition approximates to $3KF.AlF_3$. At 570°, there is also evidence of the formation of a second compound—**potassium enneafluodialuminate,** $2AlF_3.3KF$, or $K_3Al_2F_9$, the potassium analogue of chiolite—on the cooling curve of mixtures with 25 to 40 mol per cent. of aluminium fluoride There is also a break in the cooling curve of $AlF_3.3KF$ at about 302°, corresponding with the formation of a polymorphic variety analogous to that observed with cryolite. Mixtures of the two fluorides with 35 mol per cent. of aluminium fluoride are rose-coloured.

According to J. J. Berzelius, the precipitated forms of the potassium fluoaluminates are gelatinous colloids with similar properties. They dry to white powders which give off their water at a red heat. They are decomposed with the evolution of hydrofluoric acid, when boiled with sulphuric acid, and aluminium hydroxide is precipitated from the soln. by ammonia. J. L. Gay Lussac and L. J. Thénard add that the gelatinous precipitate is but sparingly soluble in acids, and still less so in water. According to E. Baud, 100 grms. of water at 16° dissolve 0·385 grm. of the precipitated $AlF_3.3KF.3\frac{1}{2}H_2O$; the heat of soln. is −20·22 Cals., and the heat of formation, 18·81 Cals. The m.p. of potassium hexafluoroaluminate is 1035°. A. Duboin has examined the optical properties of potassium cryolite; the double refraction is feebly negative, and while not establishing its isomorphism with cryolite, he says the two salts are probably isomorphous.

N. A. Puschin and A. V. Baskoff obtained fusion curves for mixtures of aluminium fluoride with rubidium and cæsium fluorides; the curves are, in general, similar to those obtained with potassium fluoride. With rubidium fluoride there is a eutectic at 790° with 6·5 molar per cent. of aluminium fluoride; a maximum at 985° corresponding with the m.p. of **rubidium hexafluoaluminate,** $3RbF.AlF_3$, or Rb_3AlF_6; a second eutectic at 570°, and a break in the cooling curve of the hexafluoride at 350° is taken to represent a polymorphic transformation. Mixtures with about 35 mol per cent. of aluminium fluoride are rose-coloured. Similarly with cæsium fluoride; there is a eutectic at 685° with 5·5 mol per cent. of aluminium fluoride; a maximum at 823° corresponding with the m.p. of **cæsium hexafluoaluminate,** $3CsF.AlF_3$, or Cs_3AlF_6; a eutectic at 490°; and a break in the cooling curve of the hexafluoride corresponding with a polymorphic transformation. Mixtures with up to 15 mol per cent. of aluminium fluoride are green; with 22·5 to 25 mol per cent., colourless; with 28·5 to 31·5 mol per cent., rose-red; and with 40 mol per cent., colourless; N. A. Puschin and A. V. Baskoff say that besides $Na_3Al_2F_9$ and $K_3Al_2F_9$ there is evidence of the formation of **rubidium enneafluodialuminate**, $Rb_3Al_2F_9$, but the compounds themselves have not been examined, and the evidence is inadequate. No solid soln. were observed with mixtures of aluminium and the alkali fluorides. The double compounds of the alkali and aluminium fluorides of the cryolite type M_3AlF_6, or $3RF.AlF_3$,

	LiF	NaF	KF	RbF	CsF
M.p.	800°	1020°	1035°	985°	823°
Transformation .	--	600°	300°	350°	—

J. J. Berzelius prepared pale bluish-green needle-like crystals of **cupric fluoaluminate** which he did not analyze. The crystals dissolve slowly in water; and R. F. Weinland and O. Köppen [8] found that aluminium fluoride unites with cupric fluoride to form three double salts. **Undecahydrated cupric heptafluoaluminate**, $AlF_3.2CuF_2.11H_2O$, or $Cu_2AlF_7.11H_2O$, is obtained from soln. containing 1 mol per cent. aluminium fluoride to 2 or more mol per cent. copper fluoride. It crystallizes in spherical aggregates of blue leaflets and does not effloresce over sulphuric acid. **Octodecahydrated cupric dodecafluoaluminate**, $2AlF_3.3CuF_2.18H_2O$, crystallizes in deep blue prisms resembling feldspar, from soln. containing 2 mol per cent. aluminium fluoride to 3 mol per cent. copper fluoride in the presence of only small quantities of hydrofluoric acid. If much acid is present, **octohydrated cupric hydrohexafluoaluminate**, $AlF_3.CuF_2.HF.8H_2O$, is formed; this crystallizes in large, blue rhombohedra from soln. containing 1 mol per cent. aluminium fluoride to 1 mol per cent. or less of copper fluoride and an excess of hydrofluoric acid, and effloresces rapidly on exposure to the air with evolution of water and hydrofluoric acid.

It is somewhat doubtful if double compounds of aluminium fluoride with the fluorides of the alkaline earths have been prepared. Fused mixtures of calcium and aluminium fluorides have a eutectic between 815° and 820°. P. Pascal and A. Jouniaux's equilibrium diagram between cryolite and fluorspar is shown in Fig. 6, where the dotted lines represent the solidus curves, the continuous lines the liquidus curves. P. P. Fedotieff and W. P. Ilinsky found the typical V-curve between calcium and aluminium fluorides with the eutectic at about 805° and 52 per cent. of aluminium fluoride. They also studied the m.p. of ternary mixtures of aluminium, sodium, and calcium fluorides. The results are shown in Fig. 58; the shaded portions of the diagram were not explored. F. Röder [9] prepared crystals of **barium fluoaluminate** by fusing a mixture of cryolite with about $1\frac{1}{2}$ times its weight of barium chloride, and 10 times its weight of sodium chloride. The composition of the crystals did not agree closely with the formula $BaF_2.AlF_3$. Similar results were obtained with **strontium fluoaluminate**. It is probable that the product in each case was a solid soln. of mixed crystals of two salts. The product was attacked by water.

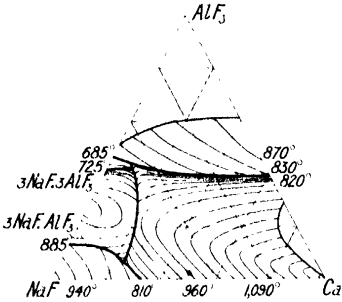

FIG. 58.—Fusion Curves in the Ternary System: CaF_2 $NaF—AlF_3$.

A. Nöllner digested powdered cryolite for three months at 100° with a conc. soln. of calcium chloride, and, after washing and drying the product at 100°, he noted that about five-sixths of the sodium had been replaced by calcium. He represented the product as $3(\frac{1}{6}Na\frac{5}{6}Ca)F.AlF_3.H_2O$; and the residue remaining after a six days' digestion at 180°, by $3(\frac{1}{3}Na\frac{2}{3}Ca)F.AlF_3.\frac{1}{2}H_2O$. There is possibly here a reversible reaction: $3NaF.AlF_3+CaCl_{2aq.}\rightleftharpoons 2NaCl_{aq.}+NaF.CaF_2.AlF_3$. The reaction can be completed if the calcium chloride be in sufficient excess; indeed, J. Lemberg completed the conversion by digesting powdered cryolite for a month with a conc. soln. of calcium chloride.

According to W. Flight's analysis, the mineral *evigtokite* found in the Greenland cryolite bed has a composition corresponding with **dihydrated calcium heptafluoaluminate,** $AlF_3.2CaF_2.2H_2O$, or $Ca_2AlF_7.2H_2O$. The mineral *pachnolite*—from πάχνη, frost—is regarded as **hydrated sodium calcium hexafluoaluminate,** $NaF.CaF_2.AlF_3.H_2O$. It was discovered by H. Kopp at Ivigtut, Greenland; F. Wöhler called it *pyroconite*—from πύρ, fire; κονία, powder—because it falls to powder when ignited. Analyses were made by H. Kopp, F. Wohler, G. Hagemann, and G. A. König. According to P. Groth, the crystals are monoclinic with axial ratios $a:b:c=1·1626:1:1·5320$, and $\beta=89° 40'$; the hardness is 3-4; the sp. gr. 2·929, according to F. Wöhler, and 2·923, according to H. Kopp; and index of refraction for sodium light 1·4119, according to O. B. Böggild. H. Kopp noted that, when heated, hydrofluoric acid and water are given off. According to H. Kopp, the ratio Na : Ca is as 4 : 3, and, according to G. von Rath, as 1 : 1. The mineral has been reported from Ivigtut in Greenland, and St. Peter's Dome in Colorado. E. S. Larsen and co-workers found a mineral which they called *creedite* in the fluorite deposits of Creede Quadrangle, Colorado. W. F. Foshag also examined the mineral. Its composition corresponds with $2CaF_2.2Al(OH, F)_3.2H_2O.CaSO_4$, which recalls the doubled formula of pachnolite, $2CaF_2.2AlF_3.2H_2O.2NaF$. It occurs in radiated masses which are colourless, sometimes showing delicate purple bands. The crystals are monoclinic with axial ratios $a:b:c=1·16199:1:1·1597$, and $\beta=85° 30'$. The cleavage is pinacoidal, parallel to the (100)-face. The optic axial angles for Li-, Na-, and Tl-light are respectively $2\gamma=64° 30'$, 64° 22', and 64° 20'. The sp. gr. is 2·713 to 2·730. The indices of refraction are $\alpha=1·461$, $\beta=1·478$, and $\gamma=1·485$, The optical character is negative. The analogous mineral *thomsenolite* has a similar composition; and, according to J. A. Krenner, it crystallizes in the monoclinic system with the axial ratios $a:b:c=0·9975:1:1·0329$, and $\beta=86° 48'$; the hardness is 2; and the sp. gr. between 2·93 and 3·0. O. B. Böggild gives the indices of refraction for sodium light as $\alpha=1·4072$; $\beta=1·4136$; and $\gamma=1·4150$. It occurs at Ivigtut in Greenland; St. Peter's Dome in Colorado; the Urals in Russia; and a sample has been reported from Japan; it was also described by E. Sharsen and R. C. Wells. The white earthy mineral resembling china clay, called *gearksutite*, has a composition corresponding with $Al(F.OH)_3.CaF_2.H_2O$. It consists, according to P. Groth, of very small needles with a feeble double refraction. It occurs at Ivigtut and Evigtokit, in Greenland; St. Peter's Dome in Colorado; and in the Urals in Russia. The monoclinic crystals of *prosopite* have the composition $2Al(F, OH)_3.Ca(F, OH)_2$, and, according to A. des Cloizeaux, the axial ratios $a:b:c=1·3188:1:0·5950$, and $\beta=85° 40'$; the hardness is between 4 and 5; and the sp. gr. 2·88-2·89. It occurs at Altenburg in Saxony; at Schlaggenwald in Bohemia; St. Peter's Dome in Colorado; Tovele in Utah; and at Mount Bischoff in Tasmania. A form of pachnolite contaminated with ferruginous matters—*e.g*, ochre—cryolite was called *hagemannite* by C. U. Shepard. F. Johnstrup regards it as a decomposition product of cryolite and iron spar. Octahedral crystals, white or colourless, of *ralstonite* occur coloured more or less yellow with iron oxide, in the cryolite beds at Ivigtut in Greenland; at St. Peter's Dome in Colorado; and in Japan. The hardness is between 4 and 5; the sp. gr. 2·6. According to O. G. Nordenskjöld, S. L. Penfield and D. N. Harper, and K. Jimbo, the composition approximates $(Na_2, Ca, Mg)F_2.3Al(F, OH)_3.2H_2O$, or $(Na_2, Mg)F_2.3Al(F, OH)_3.2H_2O$. A. Nöllner prepared **magnesium sodium fluoaluminates,** $AlF_3.3(\frac{1}{6}Na\frac{5}{6}Mg)F.H_2O$, and $AlF_3.3(\frac{1}{3}Na\frac{2}{3}Mg)F.H_2O$, respectively with five-sixths and two-thirds of the sodium in cryolite replaced by magnesium by digesting powdered cryolite with a conc. aq. soln. of magnesium chloride respectively for three months at 100°, and for six days at 180°. By reheating the products of these operations with conc. aq. soln. of calcium chloride, A. Nöllner obtained triple salts, **magnesium calcium sodium fluoaluminates**—$AlF_3.3(\frac{3}{12}Na\frac{2}{12}Ca\frac{7}{12}Mg)F.H_2O$ and

$AlF_3.3(\frac{3}{12}Na\frac{4}{12}Ca\frac{5}{12}Mg)F.H_2O$. F. Röder also prepared crystals of **magnesium fluoaluminate** analogous with those of barium fluoaluminate.

J. J. Berzelius[10] evaporated a soln. of zinc oxide and alumina in hydrofluoric acid, and obtained long, colourless, needle-like crystals probably corresponding with **zinc octofluodialuminate,** $ZnF_2.2AlF_3$, or $ZnAl_2F_8$, which were soluble in water, ammonia precipitated a hydrated zinc aluminate, or a mixture of zinc and aluminium hydroxides from the aq. soln. R. F. Weinland and O. Köppen prepared **heptahydrated zinc pentafluoaluminate,** $AlF_3.ZnF_2.7H_2O$, by mixing soln. of aluminium hydroxide and of zinc hydroxide or carbonate in dil. hydrofluoric acid, and evaporating over lime. The product can be crystallized in colourless needle-like crystals from dil. hydrofluoric acid. Small, greenish-white, rhombohedral crystals of **heptahydrated ferrous pentafluoaluminate,** $FeF_2.AlF_3.7H_2O$, were obtained in a similar way. These crystals do not oxidize on exposure to air, or effloresce over sulphuric acid. Green crystals of **heptahydrated nickel pentafluoaluminate,** $NiF_2.AlF_3.7H_2O$; and reddish-white crystals of **heptahydrated cobalt pentafluoaluminate,** $CoF_2.AlF_3.7H_2O$, were similarly obtained by R. F. Weinland and O. Köppen. White crystals of **thallous dodecafluoaluminate,** $3TlF.3AlF_3$, were prepared by F. Ephraim and P. Barteczko by the action of a soln. of thallous fluoride in hydrofluoric acid upon aluminium hydroxide; and by the evaporating on a water-bath a soln. of the theoretical quantities of the component salts in just sufficient water for the dissolution. The crystals are so stable that they are not completely decomposed by heating them with a soln. of sodium carbonate, or by heating with sulphuric acid. F. Fischer and K. Thiele obtained evidence of the existence of a *lead fluoaluminate* when lead carbonate is dissolved in a soln. of alumina in an excess of hydrofluoric acid.

§ 15. Aluminium Chloride

Several investigators have reported the formation of an **aluminium subchloride**, $AlCl_2$, or AlCl, possibly analogous with indium monochloride or indium and gallium dichlorides in the same family group. Thus, C. Friedel and L. Roux [1] claim to have made it by passing the vapour of aluminium chloride over metallic aluminium heated just to the fusion point. The brownish-grey substance which is formed contains aluminium, chlorine, and silicon. If aluminium and aluminium chloride are heated at 300°, in sealed tubes filled with carbonic anhydride, there is no appreciable action, but at 360° (in the vapour of mercury) the aluminium is slightly attacked, and large crystals of pure aluminium chloride condense on the cool upper part of the tube. When the tubes are heated by the vapour of sulphur, the aluminium is strongly attacked, and a greyish substance with a somewhat metallic appearance is deposited on the sides of the tube. This substance decomposes water with evolution of hydrogen, and contains silicon, chlorine, and aluminium. C. Formenti and M. G. Levi also reported the formation of hydrated aluminium subchloride by the action of metallic aluminium on a solution of aluminium chloride and the simultaneous evolution of hydrogen. L. F. Nilson and O. Pettersson say that the origin of the grey substance in C. Friedel and L. Roux's experiments must be attributed to the presence of traces of silicon possibly forming aluminium silicide ; and the lower proportion of chlorine in the product, to the formation of an oxychloride ; and they add that "there is no reason to believe in the existence of any aluminium chloride lower than $AlCl_3$".

The preparation of aluminium chloride.—Anhydrous aluminium chloride is obtained by the action of chlorine or hydrogen chloride on the metal or alloys of the metal, and also, under special conditions, on the oxide. In 1860, F. Wöhler[2] prepared aluminium chloride by passing a stream of chlorine over heated aluminium; and the product sublimes. Aluminium leaf does not inflame of itself in chlorine gas, but R. Böttger did get it to inflame when in contact with brass. C. A. Matignon says, that if the powdered metal, which has begun to burn in air, be immersed in chlorine or the hydrogen chloride, it continues to burn brilliantly. H. Gautier and G. Charpy found aluminium did not inflame in boiling liquid chlorine, but at −20° aluminium inflames with incandescence. H. D. Gibbs made aluminium chloride by the action of chlorine on aluminium below 0°. J. B. Cohen says that thoroughly dried hydrogen chloride does not attack aluminium, but it does so if moist; and P. Askenasy patented a process for preparing aluminium chloride, by passing gaseous hydrogen chloride over the metal heated by a sulphur-bath. G. Gore found that aluminium dissolves in liquid hydrogen chloride, forming a colourless solution. G. Gustavson, L. F. Nilson and O. Pettersson, R. Escales, E. Köhn-Abrest, and F. Stockhausen and L. Gattermann made aluminium chloride by passing chlorine or hydrogen chloride over aluminium heated in a wide glass tube. L. Gattermann's directions are:

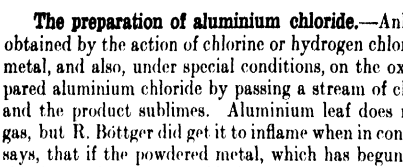

FIG. 59.—The Preparation of Aluminium Chloride.

> A hard glass tube—1·5 to 2 cms. diameter—is drawn to a narrow tube at one end which is to be connected with a train of two wash-bottles, containing sulphuric acid and connected with a generator delivering hydrogen chloride. The wash-bottles should be fairly large since the acid is liable to foam with a rapid current of hydrogen chloride. The wide end of the hard glass tube is fitted by means of a cork into a wide-necked bottle; the cork is also fitted with an exit tube, 8 mm. in diameter, *aa*, extending from the middle of the bottle, and leading to the fume chamber. An asbestos board *A* is also arranged as in Fig. 59, to protect the bottle from the heat of the furnace. The tube is fitted with an asbestos plug, then with enough aluminium shavings to half fill the tube when laid horizontally, and finally a second asbestos plug is placed at the end of the layer of aluminium shavings. The shavings should have been previously washed free from oil or grease by boiling them with alcohol, and then drying at 120° in an air-bath. The tube is then laid in the furnace as indicated in Fig. 59 with the asbestos board and bottle as close to the furnace as possible. A rapid stream of hydrogen chloride is passed through the apparatus to drive out the air as shown when the exit gas is completely absorbed by water. The tube is then heated throughout its entire length first with a small flame and then with a gradually increasing flame. The vapours of aluminium chloride collect in the bottle, and the reaction is ended as soon as the aluminium has disappeared from the glass tube. The aluminium chloride is preserved by well closing the bottle, or in a desiccator. L. Gattermann states that for success, the following points require attention: (1) All parts of the apparatus must be perfectly dry. (2) The air must be removed as completely as possible, since, otherwise, an explosion of oxygen and hydrogen may take place. (3) The portion of the tube extending beyond the furnace must be as short as possible, to prevent the aluminium chloride from condensing in it, which results in a stopping up of the apparatus. In order that the cork may not burn, it is protected by an asbestos plate, provided with a circular hole in the centre. (4) The aluminium must not be heated to melting. If this should happen at any particular point, the flames must be immediately lowered. (5) The hydrochloric acid current must be *extremely* rapid. One should not be able to count single bubbles of the gas, but they should follow one another uninterruptedly. The evolution of a small quantity of a smoky vapour from the outlet-tube will always occur, but the greatest part of the aluminium chloride is condensed even if the hydrogen chloride rushes through the wash-bottles. Should the first experiment be unsuccessful, in consequence of a stoppage of the tube, the method for correcting this will readily suggest itself.

H. N. Warren heated an alloy of aluminium with 90 per cent. of iron in a stream of chlorine, and purified the product by redistillation over iron turnings; and

C. F. Mabery heated an alloy of aluminium with 60 to 86 per cent. of copper in a graphite retort in a stream of hydrogen chloride and claimed that the product was free from iron and silicon. H. Rose found aluminium metal reduced potassium chloride to the metal with the formation of aluminium chloride; F. R. Michel obtained a similar result with sodium chloride; F. Flavitzky, with zinc chloride; and A. Cossa, with mercuric chloride. Neither F. Wöhler nor F. Flavitzky obtained an appreciable reduction of magnesium chloride by aluminium. The Aluminium Co. has patented the production of the chloride from aluminium dross. B. T. Brooks treated the molten metal with chlorine under press.

In 1825, H. C. Oersted first prepared anhydrous aluminium chloride by passing chlorine gas over a heated mixture of alumina with carbon. True, R. Weber has shown that at a white heat, a perceptible quantity of aluminium chloride is formed by the action of chlorine gas on alumina, $2Al_2O_3+6Cl_2=4AlCl_3+3O_2$, but the reaction is incomplete, and it proceeds with great difficulty, in marked contrast with the comparatively vigorous action of chlorine on a heated mixture of alumina and carbon whereby carbon monoxide is simultaneously formed: $Al_2O_3+3C+3Cl_2=3CO+2AlCl_3$. The heat of formation of aluminium oxide, Al_2O_3, is 391·6 Cals.; and of aluminium chloride, $AlCl_3$, 161·4 Cals. Consequently, the heat of the reaction: $Al_2O_3+3Cl_2=2AlCl_3+3O$, is $322{\cdot}8-380{\cdot}2=-57{\cdot}4$ Cals., so that the reaction is endothermal. The heat evolved during the formation of carbon monoxide is 29·2 Cals., so that in the reaction: $Al_2O_3+3Cl_2+3C=3CO+2AlCl_3$, $322{\cdot}8+87{\cdot}6-380{\cdot}2=30{\cdot}2$ Cals. are evolved. Hence, it may be said that the energy evolved during the combustion of the carbon is utilized in promoting the decomposition of alumina.

F. Wohler recommended rubbing precipitated aluminium hydroxide into a thick paste with powdered charcoal, sugar, and oil. The mixture was carbonized by heating it in a covered crucible, and then packed into a porcelain tube, connected at one end with a tube delivering dried chlorine, and at the other end with a tubulated glass vessel for the escape of the gas. As soon as the tube is filled with chlorine gas, heat is applied, and aluminium chloride carried along by the stream of carbon monoxide, condenses partly as a powder in the globe, and partly in transparent yellow drops which solidify to a crystalline solid at the end of the porcelain tube which may thereby be choked up. According to H. St. C. Deville, the carbon monoxide is usually accompanied by some silicon tetrachloride and possibly also carbonyl chloride. At the end of the operation, the solid is detached from the tube by a strong iron wire, and mixed with the powder which collects in the receiver. J. von Liebig recommended purifying the product by sublimation in a small retort. Any oxidizing gases present should be removed, and P. A. Favre accordingly recommended heating the chlorine with some producer gas so as to remove the free oxygen. If the alumina be contaminated with potassium sulphate, J. von Liebig showed that some potassium sulphide or sulphur chloride may be formed and that the latter will contaminate the aluminium chloride. Hence, J. von Liebig takes special precautions to ensure the absence of sulphates, and he mixed an aq. soln. of aluminium chloride with powdered sugar or starch, and ignited the dried mass in a closed vessel. The carbonized mixture was then treated with chlorine as in F. Wohler's process. R. Bunsen, and H. St. C. Deville have described apparatus for the preparation of aluminium chloride by this process. Crude aluminium chloride has a yellow tinge usually attributed to the presence of ferric chloride, but supposed by R. Weber to be due to the presence of an aluminium thio-chloride, or free chlorine. R. Weber recommended purifying the yellow aluminium chloride by mixing it with aluminium powder and then resubliming it under a slight press.; J. B. A. Dumas used a similar process, but the result under ordinary atm. press. is not so good as when a small press. is used. H. St. C. Deville passed the vapour of the crude aluminium chloride over heated iron turnings, which transforms any volatile ferric chloride into less volatile ferrous chloride; and any sulphur chloride into a mixture of ferrous chloride and sulphide, $FeCl_2$ and FeS.

The formation of metal chlorides by the action of chlorine on a heated mixture of the oxide and carbon is sometimes called *Oersted's reaction*. H. St. C. Deville showed that gaseous hydrogen chloride acts in a similar manner to chlorine. The reaction also proceeds if volatile carbon compounds be mixed with the chlorine or hydrogen chloride which is passed over the heated oxide—for instance, P. A. Favre conducted a mixture of naphthalene vapour and hydrogen chloride over heated alumina; and H. N. Warren used a mixture of petroleum vapour and chlorine or hydrogen chloride. A carbon chloride can be used in place of the mixture of hydrocarbon and chlorine—for instance, E. Demarçay, P. Camboulives, and H. Quantin used carbon tetrachloride; E. Chauvenet, C. Baskerville, and W. Heap and E. Newbery, carbonyl chloride; and H. N. Warren, chloronaphthalene. L. Burgess heated aluminium carbide with hydrogen chloride. F. P. Venable and D. H. Jackson found the reaction is satisfactory at 450°. E. R. Wolcott heated oil-shales to get the oils, and treated the carbonaceous residue with a chloridizing agent to get aluminium chloride. A. McD. McAfee, G. H. King and G. I. Roberts, and L. S. Abbott modified the process in a number of ways. D. F. Smith and H. Essex treated aluminium carbide with chlorine. G. H. King and G. I. Roberts heated alumina over 1000° in a stream of chlorine and producer gas. For the direct preparation of aluminium chloride from clays, *vide* alumina.

Sulphur compounds can be used in place of carbon compounds—for instance, P. Curie heated alumina or china clay in a mixture of carbon disulphide and hydrogen chloride—if carbon disulphide be used alone aluminium sulphide is formed, and this is converted by hydrogen chloride into aluminium chloride; similarly, C. A. Matignon and F. Bourion heated the alumina in a mixture of chlorine and sulphur chloride: $4Al_2O_3+3S_2Cl_2+9Cl_2=8AlCl_3+6SO_2$. The Consortium für Elektrochemische Industrie Gesellschaft passed sulphur chloride and chlorine over a heated mixture of alumina and carbon. They found that the first product condensed is an addition compound of S_2Cl_2 and $AlCl_3$. The components can be separated by distillation. G. Berger and W. Kühne heated clay with pyrites at 200°, and the resulting product was mixed with carbon and heated in a stream of chlorine to volatilize the aluminium chloride. The latter was mixed with sodium and strontium chloride, fused, and electrolyzed for aluminium. According to H. B. North and A. M. Hageman, alumina is not attacked by sulphuryl chloride at 200°. F. W. Hall heated a mixture of alumina, sulphur, and chlorine. Further, H. Rose found that alumina is converted into the chloride by repeated calcination with an excess of ammonium chloride; R. Weber, and A. Daubrée used phosphorus chloride, PCl_3, and obtained both aluminium chloride and the double compound $AlCl_3.PCl_3$; while L. Troost and P. Hautefeuille found that boron trichloride, BCl_3, or silicon tetrachloride, $SiCl_4$, can be used for chlorinating alumina. G. Gore found that alumina is transformed into the chloride by liquid hydrogen chloride without passing into soln. The Armour Fertilizer Co. treated the nitride with chlorine.

E. Baud found that commercial aluminium chloride contains carbonyl chloride, and it is purified by fractional sublimation in a stream of nitrogen or hydrogen. E. Biilmann prepared sublimed aluminium chloride for use in organic chemistry by charging a test tube (0·35 × 18 cm.) with 40 grms. of aluminium chloride.

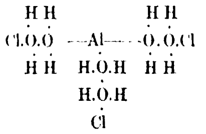
Surround the lower part of the tube with iron gauze, close the mouth of the tube with a sheet-iron cover, and wrap the upper part of the tube with cotton cloth. Heat the tube with a bunsen burner, allowing cold water to drop steadily on the cloth during the heating. Yield, 37–38 grms in 20 minutes.

According to F. Wöhler, when anhydrous aluminium chloride is exposed to the air, it rapidly deliquesces, forming a clear liquid; the chloride also dissolves in water with a hissing noise and the development of much heat. A similar soln. is obtained by dissolving the metal in hydrochloric acid, by saturating hydrochloric acid with alumina, and by the double decomposition of soln. of aluminium sulphate and barium chloride—with calcium chloride, E. Thorey[3] found a double calcium and aluminium chloride is formed. According to P. A. von Bonsdorff, when the aq. soln. is spontaneously evaporated in dry air, or, according to T. Gladycz, in vacuo, crystals of **hexahydrated aluminium chloride,** $AlCl_3.6H_2O$, are formed. E. Borsbach found similar crystals to be precipitated when hydrogen chloride is passed into or when conc. hydrochloric acid is added to a cold conc. soln. of aluminium chloride. L. M. Dennis prepared hexahydrated aluminium chloride of a high degree of purity from the salt of ordinary commercial purity by the following process:[4]

Commercial anhydrous aluminium chloride is dissolved in water, and, after being filtered through glass wool, is mixed with conc. hydrochloric acid, and the soln., cooled with a freezing mixture, is sat. with dry hydrogen chloride. The crystals which rapidly form are washed by decantation with conc. hydrochloric acid until free from iron, and the excess of acid is removed as far as possible by the aid of the pump. The crystals are then placed on porous tiles and exposed to the air until free from hydrogen chloride ; in moist air, water is absorbed, but if kept at 20° their weight becomes constant after about 48 hrs. The crystals, $AlCl_3,6H_2O$, do not change when kept over sulphuric acid, but if heated in a stream of dry hydrogen chloride, a basic salt is formed.

C. von Hauer prepared crystals of the same salt by heating aluminium hydroxide with conc. hydrochloric acid in a sealed tube, and then cooling the soln H. Howard passed hydrogen chloride into a conc. soln. of aluminium chloride, and washed the crystals which separated with a soln. of basic aluminium chloride; and G. A. Blanc obtained aluminium chloride by the action of hydrochloric acid on leucite, and saturated the hot soln. with hydrogen chloride in order to precipitate the aluminium chloride, and leave the potassium chloride in soln. According to E. Lubarsky, if dil. soln. are cooled to −8°, they deposit crystals of **enneahydrated aluminium chloride,** $AlCl_3.9H_2O$, but the equilibrium diagram of the binary system $AlCl_3-H_2O$ has not yet been explored.

The aq. soln. loses hydrogen chloride when evaporated, particularly at elevated temp., and if the evaporation is carried to dryness, J. Ordway found a basic product is formed which is completely soluble in water, and with repeated evaporation much alumina or aluminium hydroxide is formed. As in the case of magnesium chloride, the evaporation of the soln. in a stream of hydrogen chloride enables the soln. to be conc. without forming the hydroxide. H. Ley computed the degree of hydrolysis of aq. soln. of aluminium chloride from their effect on the inversion of cane sugar, and found a $\frac{1}{32}N$-soln. is 8·8 per cent. hydrolyzed, a $\frac{1}{64}N$-soln., 13·8 per cent. ; a $\frac{1}{128}N$-soln., 20·1 per cent. ; a $\frac{1}{256}N$-soln., 28·7 per cent. ; and a $\frac{1}{512}N$ soln., 41·8 per cent. hydrolyzed. The hydrolysis is thus smaller than with ferric chloride in agreement with the stronger basic properties of $Al(OH)_3$ over $Fe(OH)_3$. H. de Sénarmont found that if an aq. soln. be strongly heated in a sealed tube anhydrous alumina separates out. P. A. von Bonsdorff says that the crystals do not effloresce when confined in a desiccator over sulphuric acid, but they deliquesce rapidly in an ordinary atm. P. Sabatier observed very little change after the crystals had been confined over sulphuric acid in vacuo during the summer months. The crystals do not melt when heated, but they give off water and hydrogen chloride, leaving 21·605 per cent. of alumina as a residue in the form of the original crystals. The anhydrous chloride cannot be obtained by heating the hydrated salt. F. A. Gooch and F. M. McClenaham found that the speed of dehydration of aluminium chloride is reduced by hydrogen chloride below 130°, but above this temp., as also in air, water and hydrogen chloride are simultaneously evolved; they assume that the water is intimately associated with the chlorine in the molecular complex and can be represented by the graphic formula :



$$\begin{array}{ccc} \text{H H} & & \text{H H} \\ \text{Cl.O.O} & \text{---Al---} & \text{O.O.Cl} \\ \text{H H} & \text{H.O.H} & \text{H H} \\ & \text{H.O.H} & \\ & \text{Cl} & \end{array}$$

Contrast this with the behaviour of the hydrated barium and magnesium chlorides. **W. Madelung also worked on the constitution of aluminium chloride. E. P. Kohler has shown that aluminium chloride in aq. soln., or in any solvent known to combine with it, has a molecular weight in agreement with the formula $AlCl_3$, whereas in a saturated indifferent solvent like carbon disulphide, the molecular weight is Al_2Cl_6. It is assumed by A. S. Cushman that the linkage $-O(H_2)-O(H_2)-$ is not strong enough to hold the large complex together, while the linkage $-Cl=Cl-$ can do so.**

The properties of aluminium chloride.—According to F. Wöhler,[4] and H. St. C. Deville and L. Troost, anhydrous aluminium chloride forms colourless or white hexagonal plates which K. Seubert and W. Pollard say are composed of three individuals twinned together, and they show rhombic symmetry. The angles of extinction are 120°, and the crystals are optically negative. C. Friedel and L. Roux obtained fine crystals by heating the salt in a sealed tube to about 400°. According to F. Wöhler, hexahydrated aluminium chloride forms "regular six-sided prisms *with the terminal faces of a rhombohedron*" belonging, according to L. M. Dennis and A. H. Gill, to the trigonal system with the axial ratio $a:c=1:0·5356$, and $\alpha=111° 40'$. The double refraction is strong, and the refraction index about 1·6. W. Biltz and co-workers gave 2·398 to 2·440 at 20°/4° for the sp. gr. of aluminium chloride, and the mol. vol., 54·7; and at 190°, the sp. gr. of fused aluminium chloride is 1·33, and the mol. vol. 100. W. Biltz and A. Voigt gave for the sp. gr. 1·33 at 190°; 1·31 at 200°; 1·28 at 210°; 1·255 at 220°; and 1·23 at 230°. The coeff. of thermal expansion of the liquid is therefore 0·002.

J. von Liebig noted that when heated under atm. press., small quantities of anhydrous aluminium chloride can be volatilized without melting, but large quantities when rapidly heated, melt and boil. F. Wohler found the more or less impure salt melts when heated under petroleum, forming a brownish-red liquid which does not dissolve in the oil. In a sealed tube, K. Seubert and W. Pollard found the salt melts between 193° and 194°; and C. Friedel and J. M. Crafts give the m.p. between 186° and 190° at 2·5 atm. press. Hexahydrated aluminium chloride decomposes when heated without melting. According to J. von Liebig, anhydrous aluminium chloride boils between 180° and 185°, and C. Friedel and J. M. Crafts found the b.p. to be 167·8° at 0·33 atm. press.; 171·1° at 0·41 atm.; 175·7° at 0·57 atm.; 182·7° at 0·99 atm.; 204·2° at 2·37 atm.; 207·5° at 2·64 atm.; and 213° at 3·6 atm. press. According to L. Rotinjanz and W. Suchodsky, the critical temp. on the absolute scale is 629·5° K. and the sublimation point 456° K., and the ratio $T_c/T_b=0·724$. The sp. ht. of aluminium chloride was found by E. Baud to be 0·188. J. Thomsen found the heat of formation (Al_2, Cl_6) to be 321·87 Cals.; $(Al_2Cl_6, aq.)$, 153·69 Cals.; and $(Al_2, Cl_6, aq.)$, 475·56 Cals. M. Berthelot gives $Al(OH)_3+3HCl_{aq.}=18·6$ Cals. E. E. Somermeier found the heat of dissolution of aluminium in $HCl+19·15H_2O$ to be 128·06 Cals. per gram-atom. P. Sabatier found the heat of soln. of $AlCl_3$ in 900 mols of water to be 26·4 Cals. at 15·5°. K. Jauch found the sp. ht. of soln. with N eq. of aluminium chloride per litre to be

N	0·5	1·0	2·0	3·0	4·0
Sp. ht.	0·9593	0·9257	0·8632	0·8098	0·7630

H. St. C. Deville and L. Troost found the vapour density at 350° and at 440°, 9·34, when the calculated value for Al_2Cl_6 is 9·25. C. Friedel and J. M. Crafts also found that between 218° and 432° the chloride has a vapour density of 9·19 in accord with the formula Al_2Cl_6. According to L. F. Nilson and O. Pettersson, the chloride dissociates as the temp. approaches 758° when the vapour density is 4·802. At 800° the dissociation is complete, for the vapour density is 4·542 at 835°, and 4·557 at 943°. This corresponds with the formula $AlCl_3$, whose theoretical vapour density is 4·6. Towards 1117° there are signs of a decomposition, for the vapour density is then 4·269, 4·247 at 1244°, and 4·277 at 1260°. It is therefore inferred that the mol. has the formula Al_2Cl_6 below 440°; that it is partially dissociated $Al_2Cl_6 \rightleftharpoons 2AlCl_3$ between 440° and 600°; and above 600°, the mol. has the formula $AlCl_3$ (Fig. 60). V. Meyer and H. Zublin add that aluminium chloride is partially dissociated above 100°. A. Werner found that in pyridine soln. the mol. is probably $AlCl_3$; E. Beckmann obtained similar results for soln. in ether; and E. P. Kohler for soln. in boiling or freezing nitrobenzene. E. P. Kohler showed that the formation of addition products with pyridine and nitrobenzene vitiates the mol. wt. determinations in these solvents unless precautions be taken to correct the results. According to W. Biltz, the f.p. of aq. soln. agree with the assumption

that the mols. are associated, not less than Al_2Cl_6, but E. P. Kohler has shown that in water soln. or in any solvent that is known to combine with it, aluminium chloride has a mol. wt. corresponding with the formula $AlCl_3$, whereas in an indifferent solvent like carbon disulphide, it has the doubled mol. wt.

J. R. Collins measured the ultra-red absorption spectrum of soln. of aluminium chloride. W. Jevons found aluminium chloride becomes phosphorescent when exposed to active nitrogen. H. Buff stated that fused anhydrous aluminium chloride can be electrolyzed, but W. Hampe states that if quite pure the molten salt does not conduct electricity. W. Biltz and A. Voigt found the electrical conductivity increases from zero at ordinary temp. to 10^6 mhos at the m.p., when it drops abruptly to zero, and slowly rises again, Fig. 61.

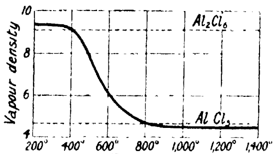


Fig. 60.—Effect of Temperature on the Vapour Density of Aluminium Chloride.

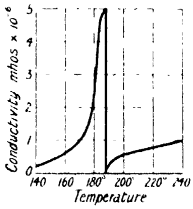

Fig. 61.—Electrical Conductivity of Aluminium Chloride.

	146°	164°	182°	189°	200°	227°	245°
Mhos × 10^6 . .	0·29	0·70	2·6	5·0	0·56	0·86	1·1

Observations were also made by A. Benrath. H. Ley found the mol. conductivity, μ, of a mol of the salt $AlCl_3$ in v litres of water to be:

v . . .	32	64	128	256	512	1024
μ . .	99·9	106·9	114·1	123·8	131·0	138·0

and he also studied the degree of hydrolysis as indicated above. According to R. J. Meyer, the eq. conductivity rises from 99·9 for a soln. of a mol of $AlCl_3$ in 32 litres to 138 for a dilution 1024 litres; so that $\lambda_{1024}-\lambda_{32}$ is 38·1, a little greater than for scandium chloride. For tervalent salts this difference usually amounts to about 26 units, and the increased value with aluminium and scandium chlorides is explained by the high ionic mobility of the hydrogen ions of the acid set free by hydrolysis. H. C. Jones and F. H. Getman have calculated the degree of hydration of the salt in conc. aq. soln. from the electrical conductivity and the f.p. of aq. soln. A. Heydweiller measured the sp. gr. and electrical conductivity of soln. of aluminium chloride. A. B. Bryan measured the conductivity of flames charged with aluminium chloride; and F. E. Bartell and D. C. Carpenter studied the rate of osmosis. F. Guthrie found that a mixture of hexahydrated aluminium chloride with three to four times its weight of ice gave a soln. at −13°. F. E. Bartell and D. C. Carpenter measured the difference of potential of water and soln. of aluminium chloride separated by a permeable membrane. F. E. Bartell and O. E. Madison found that in the osmosis of soln. of aluminium chloride, the membrane becomes electropositive to the soln., and the soln. side of the membrane is electropositive, and the osmosis is positive. F. E. Bartell and L. B. Sims studied the swelling of colloidal membranes by soln. of aluminium chloride.

G. T. Gerlach found 100 grms. of a sat. soln. contained 41·13 grms. of aluminium chloride, $AlCl_3$, at 15°, and the sp. gr. of the soln. was 1·354; aq. soln. containing

Per cent. $AlCl_3$. .	**5**	**10**	**15**	**20**	**25**	**30**	**35**	**40**
Sp. gr. . . .	**1·0361**	**1·0734**	**1·1125**	**1·1537**	**1·1968**	**1·2422**	**1·2905**	**1·3415**

F. Wöhler noted that anhydrous aluminium chloride fumes in moist air, and smells of hydrogen chloride. According to M. Berthelot, when heated with oxygen to redness, there is a partial displacement of the chlorine, either due to the formation of an oxychloride or to the balanced reaction: $2Al_2O_3+6Cl_2\rightleftharpoons4AlCl_3+3O_2$—the heat of formation of Al_2O_3 is 391·6 Cals., and of Al_2Cl_6, 301·8 Cals.

P. Hautefeuille and A. Perrey[5] prepared what they regarded as **aluminium oxychlorides** by the combustion of aluminium in a mixture of vapour of aluminium chloride and oxygen; and in a mixture of chlorine and oxygen. The composition of the products was indefinite. The white crystals are decomposed by water, and dissolve in dil. acids and alkalies. D. Tommasi reported that aluminium acts briskly on cupric chloride at ordinary temp., forming copper, hydrogen, and an aluminium oxychloride whose composition varies with the temp.; and he added that if aluminium be allowed to act on the product, an oxychloride of the composition $AlCl_3.6Al(OH)_3.6H_2O$ is produced. A soln. of this compound is decomposed by a drop of sulphuric acid with the precipitation of aluminium hydroxide; it is sparingly soluble in acid, and is possibly an isomeric modification of the hydroxide.

L. Liechti and W. Suida examined the solubility of aluminium hydroxide in soln. of aluminium chloride, and they found that when the former is added to the latter in quantity sufficient to form the basic salt $Al_2Cl_4(OH)_2$, the alumina dissolved only on heating and the soln. remained clear on cooling. To this clear soln. a further quantity of aluminium hydroxide was added sufficient to form the compound $Al_2Cl_2(OH)_4$. It was, however, found that no more alumina could be made to dissolve, the precipitate even increasing, and on filtering it was found that the soln. contained an equal number of mols of normal Al_2Cl_6 and of HCl. The nascent $Al_2Cl_2(OH)_4$ had apparently decomposed according to the following formula: $7Al_2Cl_2(OH)_4+2H_2O=5Al_2(OH)_6+2Al_2Cl_6+2HCl$. In the same way it was proved that, on adding aluminium hydroxide to $Al_2(SO_4)_3$ soln. sufficient to produce the basic compound $Al_4(SO_4)_3(OH)_6$, no alumina at all dissolved, the filtrate only containing $Al_2(SO_4)_3$. Here, too, we must suppose that the nascent basic compound decomposes as follows: $Al_4(SO_4)_3(OH)_6=Al_2(OH)_6+Al_2(SO_4)_3$. E. Schlumberger prepared a colloidal form of aluminium hydroxide which he regarded as having the composition $Al_6O_{14}H_{10}$, and he found it to dissolve in cold dil. hydrochloric acid, forming a viscous opalescent liquid which gives a gum-like coagulum supposed to be a hydrochloride $Al_6O_{14}H_{10}.HCl$, but is more likely to be colloidal alumina with adsorbed acid—similar remarks apply to the nitrate, acetate, and sulphate. According to M. Adolf and co-workers, it is impossible to remove all the chlorine from the products of hydrolysis of aluminium chloride by washing. A quantity of chlorine, which is greatly in excess of that contained in the hydrochloric acid required for peptization, always remains. On boiling well-washed aluminium hydroxide with dil. hydrochloric acid, sols of various compositions are obtained up to a limiting composition represented by the formula $[Al(OH)_3]_2$, AlOCl. Of these, two have been investigated. *Aluminium hydroxydichloride*, $AlCl_2.OH$, behaves as a ternary electrolyte, and, on dilution, it is strongly dissociated, the process being complete at a dilution 0·00106*N*. This compound shows a remarkably small degree of hydrolysis, amounting only to 0·1 per cent. at 0·068*N*, and in a 0·00106*N* soln. is only 0·25 per cent. The compound aluminyl monochloride, $Al(OH)_2Cl$ or AlOCl, behaves as a binary electrolyte. The conductivity data indicate that a complex ionization occurs in this case of the type $Al(OH)_2Cl \mid AlO$, indicating a compound in which one aluminium atom of the complex acts as the central atom of a negative complex, whilst the other furnishes a stable univalent positive ion. The peptization of aluminium hydroxide leads to a sol of the composition $2[Al(OH)_3]Al(OH)_2Cl$, and this on dilution undergoes complex ionization represented by the formulæ: (1) $10Al(OH)_3.4AlOCl.AlO \mid Cl$; (2) $12Al(OH)_3.5AlOCl.AlO \mid Cl$; (3) $16Al(OH)_3.7AlOCl.AlO \mid Cl$. On the other hand, no complex ionization of the form $Al(OH)_2 \mid AlO$ has been observed in the case of aluminium hydroxide.

According to O. C. Ralston, the reaction between moisture and aluminium chloride often does not take place at once, but the hydrochloric acid is given off slowly on standing. If the surface of a mass of anhydrous aluminium chloride is allowed to "glaze" with a coating of aluminium chloride hydrate ($AlCl_3.6H_2O$) and the mass is then sealed in a tight container, the water of the hydrate slowly diffuses to the remaining anhydrous material and reacts to form aluminium oxide and hydrochloric acid gas. As the reaction proceeds the pressure of the gas finally becomes strong enough to burst the container. A glass bottle filled with aluminium chloride which has been exposed to the open air for a few minutes before being placed in the bottle may blow its stopper in this way. Large drums filled with the commercial product have been known to "explode," probably from this cause.

When aluminium chloride is heated with water vapour, H. Kunheim noted the formation of hydrogen chloride and aluminium hydroxide. H. Rose stated that when distilled with sulphur trioxide it forms chlorine, sulphur dioxide, and aluminium sulphate. R. Weber studied the reaction between aluminium chloride and sulphur chloride, S_2Cl_2, and he observed the formation of a double compound, $2AlCl_3.SCl_4$; O. Ruff also prepared $AlCl_3.SCl_4$ by the action of sulphur chloride, SCl_2, on a soln. of aluminium chloride in sulphuryl chloride, SO_2Cl_2, thus: $3SCl_2+AlCl_3=AlCl_3.SCl_4+S_2Cl_2$. F. Wöhler, and E. Baud noted the formation of double compounds with hydrogen sulphide, $2AlCl_3.H_2S$, and $AlCl_3.H_2S$. The first-named compound is prepared with liquid hydrogen sulphide but dissociates at −45° into hydrogen sulphide and $2AlCl_3.H_2S$, which is stable at ordinary temp. and press. R. Weber also prepared $2AlCl_3.SeCl_4$ and $2AlCl_3.TeCl_4$. E. Baud, O. Ruff, and A. Adrianowsky studied the formation and properties of $2AlCl_3.SO_2$ and $AlCl_3.SO_2$. The latter is prepared by subliming aluminium chloride in a current of sulphur dioxide; it dissociates at 80°, forming $2AlCl_3.SO_2$, which can be distilled at 200°. The heat of formation of $AlCl_3.SO_2$ is 14·46 Cals., and the heat of soln. 298·62 Cals.; the heat of formation of $2AlCl_3.SO_2$ is 18·33 Cals., and the heat of soln. at 15°, 150·54 Cals. J. A. Besson prepared double compounds of aluminium chloride with thionyl bromide or thionyl chloride. F. Wohler, and A. Recoura prepared *aluminium chlorosulphate*, $Al(SO_4)Cl.6H_2O$, by the action of boiling fuming hydrochloric acid on aluminium sulphate. V. Thomas obtained the double compound $2AlCl_3.NO$ by slowly subliming aluminium chloride in an atm. of nitric oxide; and R. Weber, $AlCl_3.NOCl$, by the action of the gases from aqua regia on aluminium chloride. E. Baud found that acetylene is absorbed by anhydrous aluminium chloride in the cold, and rapidly at 70°–130°, forming a black volatile compound, $7(C_{10}H_{15\cdot6}).2Al_2Cl_6$. According to W. E. Henderson and W. C. Gangloff, dry acetylene acts on an alcoholic soln. of aluminium chloride, forming well-defined colourless crystals of $AlCl_3.2C_2H_2.2H_2O$; and with ethylene, giving $AlCl_3.3C_2H_4.H_2O$.

When an aq. soln. of aluminium chloride is treated with ammonia, aluminium hydroxide is precipitated, and J. J. Berzelius thought that the precipitate formed when insufficient ammonia is added to saturate completely the soln. is a basic chloride or oxychloride. In all probability the product is colloidal aluminium hydroxide, with adsorbed chloride. E. C. Franklin found aluminium chloride to be insoluble in liquid ammonia. According to E. Baud, if a stream of well-dried ammonia be passed over sublimed aluminium chloride much heat is evolved, the mass becomes liquid, and then solidifies to a voluminous white powder, **aluminium hexamminochloride,** $AlCl_3.6NH_3$. The last mol. of ammonia is taken up very slowly. When treated with hydrogen chloride, there is no perceptible action below −15°; at 0°, the reaction is very slow, and at 15° vigorous producing ammonium chloride, ammonia, and $6AlCl_3.NH_3$. J. M. Stillmann and M. B. Yoder found that when heated in air, ammonium chloride and alumina $Al_2O_3.H_2O$ are formed. E. Baud says the hexamminochloride is less hygroscopic than the chloride; and that on exposure to air, it absorbs moisture and loses ammonia, forming aluminium hydroxide and ammonium chloride. The heat of formation $AlCl_3, 3NH_3$ is 134·11 Cals. E. Baud noted that when the hexamminochloride is cooled with liquid ammonia, and the latter is allowed to evaporate with the temp. below −22°, **aluminium enneamminochloride,** $AlCl_3.9NH_3$, is formed with a vap. press. of 1790 mm. at 0°;

978 mm. at −10·7°; 760 mm. at −14·6°; 481 mm. at −22·3°; and 189 mm. at −37°. There is no break in the curve. The heat of formation, $AlCl_3.6NH_3+3NH_3$, is 24·81 Cals. E. Baud found that when the hexamminochloride is heated below 150°, the evolution of ammonia is not very marked, but at that temp. ammonia is evolved and **aluminium pentamminochloride,** $AlCl_3.5NH_3$, is formed. J. M. Stillmann and M. B. Yoder obtained the same product by heating the hexamminochloride for 12 hrs. at 100° in a stream of hydrogen. The heat of formation $AlCl_3.+3NH_3$ is 38·84 Cals. E. Baud obtained **aluminium triamminochloride,** $AlCl_3.3NH_3$, by heating the pentamminochloride to 275°; and H. Rose, and J. F. Persoz, by treating aluminium chloride with ammonia until the mass becomes liquid. The heat of formation $AlCl_3+3NH_3$ is 83·77 Cals. J. M. Stillmann and M. B. Yoder heated aluminium hexamminochloride in an atm. of hydrogen for 10 hrs. between 200° and 240°. Analyses of the semi-liquid hygroscopic mass agreed with **aluminium diamminochloride,** $AlCl_3.2NH_3$. G. L. Clark reported the temp. at which these different ammines dissociate at 100 mm. press., to be −13° for the ennea-ammine; 77° for the hexammine; 280° for the pentammine; 427° for the triammine; and 752° for the monammine. According to E. Baud, if aluminium triamminochloride be heated to 280° it melts, and at 400°, distils as a colourless liquid which rapidly solidifies to a white translucent mass with the composition $6AlCl_3.NH_3$—**aluminium hexita-amminochloride.** H. Rose obtained a similar product by the distillation of one of the higher ammino compounds in a stream of hydrogen. H. Rose assigned to this product the formula $AlCl_3.NH_3$, but E. Baud showed that an excess of ammonia was present in H. Rose's product, and that with repeated distillation $6AlCl_3.NH_3$ is formed. By distilling $6AlCl_3.NH_3$ in a stream of ammonia, the product contains $AlCl_3+2·33NH_3$ and evolves 38·83 Cals.—but is not a chemical individual. The compound forms a clear soln. with water. H. Rose reported that aluminium chloride absorbs about 3·67 per cent. of phosphine in 5 hrs. in the cold, but is sublimed in a stream of the gas, forming crystals of the double compound $3AlCl_3.PH_3$; small quantities of this compound dissolve in water with the evolution of phosphine not spontaneously inflammable in air, larger quantities give the spontaneously inflammable gas. The latter gas is also obtained when the compound is treated with ammonia. E. Baudrimont, and R. Weber prepared $AlCl_3.PCl_5$; and W. Casselmann, $AlCl_3.POCl_3$. With carbonyl chloride, E. Baud prepared the three compounds: $2AlCl_3.5COCl_2$ melting at −2°; $2AlCl_3.3COCl_2$; and $4AlCl_3.COCl_2$—the two last-named compounds are said to occur in commercial aluminium chloride.

Hexahydrated aluminium chloride is soluble in alcohol; and in ether. According to F. S. Havens, this salt is quite insoluble in alcohol; and he further found that it is quite insoluble in aq. ether saturated with hydrogen chloride, and if ether be added to an aq. soln. of this salt, and the well-cooled liquid be sat. with hydrogen chloride, hexahydrated aluminium chloride is precipitated while the chlorides of beryllium, zinc, copper, mercury, and bismuth remain in soln. W. Eidmann says hexahydrated aluminium chloride is insoluble in methylal; and A. Werner, in pyridine, and benzene. A number of double salts of aluminium chloride with the metal chlorides, and with various organic compounds—and chlorides, ketones, esters, nitro-compounds, amines, etc., is known. When bottles of aluminium chloride are sealed with paraffin, the salt blackens the seal. A soln. of aluminium chloride may segregate into two layers on standing. Most of the chloride remains with the lower darker-coloured layer.

According to F. Wöhler, aluminium chloride is reduced when heated with potassium, but not under naphtha. N. N. Beketoff did not succeed in reducing aluminium chloride by heating it with zinc. A. Daubrée found that when calcined to redness with calcium oxide it forms corundum; and with magnesium oxide, corundum and spinel. A soln. of aluminium chloride acts as an antiseptic and is utilized in dyeing. The addition of aluminium chloride accelerates the hydration of calcium oxide, of plaster of Paris, $CaSO_4.\frac{1}{2}H_2O$, and of Portland cement—in the latter case provided less than 2·91 per cent. be used. The aluminium chloride retards the hydration of anhydrous calcium sulphate—*Estrichgips*. A mixture with thionyl chloride, $SOCl_2$, or sulphur monochloride, S_2Cl_2, develops chlorine. These and many other reactions, which either do not occur at all or proceed with difficulty, will readily take place if aluminium chloride be present as a catalytic agent. O. Ruff assumes that an intermediate compound is formed—$AlCl_3.SCl_4$. Similarly, thionyl chloride and sulphur give sulphur chloride and sulphur dioxide, and the reactions are symbolized: $AlCl_3+SOCl_2 \rightleftharpoons AlCl_3.SO+Cl_2$, followed by $AlCl_3.SO_2 \rightleftharpoons AlCl_3+SO_2$. Analogous reactions accelerated by aluminium chloride are the formation of iodine chloride and sulphur dioxide from sulphuryl chloride and iodine; of molybdenum pentachloride from thionyl chloride and molybdenum dichloride: of hydrogen chloride, sulphur dioxide, and sulphur from thionyl chloride, $SOCl_2$, and hydrogen sulphide; and of sulphur chloride from sulphur and a soln. of phosphorus pentachloride in phosphoryl chloride at 100°.

Aluminium chloride is also a valuable catalytic agent in the so-called Friedel and Crafts' reaction—typified by the synthesis of toluene, $C_6H_5.CH_3$, by passing the vapour of methyl chloride, CH_3Cl, into a boiling soln. of anhydrous aluminium chloride in benzene: $C_6H_6+CH_3Cl=HCl+C_6H_5.CH_3$; the aluminium chloride acts as a carrier, possibly by forming an unstable intermediate compound with benzene and methyl chloride. The subject was discussed by J. F. Norris. Aluminium chloride is thus used as a catalytic agent and also as a condensing agent in organic chemistry. It was formerly employed in the preparation of aluminium. The largest amount of aluminium chloride is used in refining petroleum, when it converts the unsaturated components into saturated compounds; it converts high boiling hydrocarbons into others of low b.p.; and it removes sulphur, partly as hydrogen sulphide and partly as aluminium sulphide.

Chloroaluminates.—A number of double compounds of aluminium chloride with other metallic chlorides and ammonium chloride has been prepared—principally by E. Baud.[6] **Ammonium tetrachloroaluminate,** $NH_4Cl.AlCl_3$, or NH_4AlCl_4, was made by heating the calculated quantities of the component salts in a closed vessel at 250° or 300°. The mixture is melted, and, on cooling, forms a crystalline mass which can be distilled unchanged at a red heat in a stream of hydrogen or nitrogen. The heat of formation $NH_4Cl+AlCl_3$ is 13·26 Cals., the heat of soln. at 15°, 60·48 Cals. This compound was also prepared by J. Kendall and co-workers, and its m.p. found to be 304°.

J. Kendall and co-workers made **lithium tetrachloroaluminate,** $LiCl.AlCl_3$. F. Wöhler found that when the vapour of aluminium chloride is passed over heated sodium chloride a yellow compound is formed which does not give off aluminium chloride when strongly ignited, and which dissolves in water, forming a soln. which yields crystals of sodium chloride on evaporation. H. St. C. Deville and H. Rose also prepared the same compound. The composition is represented by the formula $NaCl.AlCl_3$, or $NaAlCl_4$—**sodium tetrachloroaluminate.** The compound was once used in the manufacture of aluminium and was made industrially by heating a mixture of alumina, carbon, and sodium chloride in a clay retort to a white heat in a stream of chlorine when the sodium tetrachloroaluminate sublimes. M. Dullo made it by heating a mixture of sodium chloride, carbon, and clay in a current of chlorine until silicon tetrachloride begins to form, indicating that all the available alumina has been transformed into sodium chloroaluminate. J. Kendall and co-workers made this salt; R. Bunsen obtained the same compound by fusing together the component salts; and said that the m.p. is below 200°, while H. St. C. Deville said about 185°. E. Baud gives the heat of formation $AlCl_3+NaCl$ as 5·95 Cals., and the heat of soln. at 15° as 70·71 Cals. H. St. C. Deville found that when the vapour is passed over strongly heated iron, ferrous chloride and an alloy of aluminium and iron is formed; and when heated with potassium hydrogen sulphate, thionyl chloride and chlorine are formed. H. Bassett observed that the salt is reduced to aluminium by boron, arsenic, antimony, tin, zinc, mercury, and by the amalgams of tin, zinc, and antimony. R. Bunsen obtained aluminium by the electrolysis of the fused salt.

E. Baud also found that the alkali chlorides of the type $MCl.AlCl_3$ absorb ammonia to form **alkali hexammino-tetrachloroaluminates,** $MCl.AlCl_3.6NH_3$. The heats of formation and soln. of the ammonium compound are respectively 126·04 Cals., and −2·73 Cals.; of the sodium compound, 177·93 Cals. and 5·61 Cals.; and of the potassium compound 126·08 Cals., and −3·04 Cals. The salt dissolves in water and the soln. deposits sodium chloride on evaporation. H. C. Jones and K. Ota found the electrical conductivity of dil. soln. is very little different from the calculated conductivities of the components, but with 1·0 to 1·5*N*-soln. the conductivity deviates 13 per cent. from the calculated value. E. Baud made **sodium enneachlorodialuminate,** $3NaCl.2AlCl_3$, or $Na_3Al_2Cl_9$, by heating aluminium chloride with sodium chloride to about 500°; the molten portion has the composition $AlCl_3.1\frac{1}{2}KCl$, while the excess of alkali chloride remains undissolved. The heat of formation $1\frac{1}{2}NaCl+AlCl_3$ is 7·64 Cals., and the heat of soln. at 15°, 68·48 Cals. By fusing together calculated quantities of the component salts, E. Baud made $3NaCl.AlCl_3$, **sodium hexachloroaluminate,** with the heat of formation 9·6 Cals., and a heat of soln. at 15°, 54·86 Cals.

R. Weber made **potassium tetrachloroaluminate,** $KCl.AlCl_3$, or $KAlCl_4$, by fusing together the component salts, and by heating potassium chloride with the double compounds of aluminium chloride with phosphorus pentachloride or sulphur dichloride. J. Kendall and co-workers made this salt. According to A. F. E. Degen, if potash be present when Oerstedt's process is used for making aluminium chloride, there are formed colourless drops of aluminium tetrachloroaluminate which solidify, on cooling, to a crystalline mass which deliquesces slowly in air, and dissolves in water with the evolution of heat. E. Baud gives for the heat of formation 13·19 Cals., and for the heat of soln. at 15°, 60·22 Cals. E. Baud made **potassium enneachlorodialuminate,** $K_3Al_2Cl_9$, or $3KCl.2AlCl_3$, by a process similar to that used for the corresponding sodium salt; its heat of formation $1\frac{1}{2}KCl+AlCl_3$ is 15·26 Cals., and the heat of soln., at 15°, 7·64 Cals. Similar remarks apply to the preparation of **potassium hexachloroaluminate,** $3KCl.AlCl_3$, or K_3AlCl_6, with a heat of formation 18·318 Cals., and a heat of soln. at 15°, 46·652 Cals. The evidence that these are definite compounds is not conclusive. E. H. Ducloux prepared colourless crystals of **cæsium chloroaluminate,** thought to be $CsCl.AlCl_3$. J. Kendall and co-workers made **cuprous tetrachloroaluminate,** $CuCl.AlCl_3$, melting at 233°. E. Chauvenet, P. Job and G. Urbain established the existence of **cupric octochloroaluminate,** $CuCl_2.2AlCl_3$, and of **cupric heptachloroaluminate,** $2CuCl_2.AlCl_3$, by thermochemical analyses of the aq. soln. E. Baud reported the formation of **silver tetrachloroaluminate,** $AgCl.AlCl_3$, or $AgAlCl_4$, when the two components are heated in a sealed tube at 300°; the product is less stable than the corresponding alkali salts; its heat of formation is 2·5 Cals., and its heat of soln. at 22°, 75·72 Cals. J. Kendall and co-workers made this salt. E. Baud also made **calcium octodecachlorotetraluminate,** $4AlCl_3.3CaCl_2$, with a heat of formation 18·56 Cals., and a heat of soln. at 16°, 346·8 Cals.; it melts below 300°. For the chloroaluminate $3CaO.CaCl_2.Al_2O_3,10H_2O$, *vide* calcium aluminate. The corresponding **strontium octodecachlorotetraluminate,** $4AlCl_3.3SrCl_2$, also melts below 300°, its heat of formation is 17·42 Cals., and its heat of soln. at 19°, 328·78 Cals. J. Kendall and co-workers, and E. Baud made **barium octochlorodialuminate,** $BaCl_2.2AlCl_3$. The latter found the m.p. to be 290°. It crystallizes in silky needles recalling some native varieties of spinel; its heat of formation is 5·39 Cals., and when heated to 500°, it loses some aluminium chloride, and forms **barium octodecachlorotetraluminate,** $4AlCl_3.3BaCl_2$, with a heat of formation of 14·6 Cals. J. Kendall and co-workers made **magnesium octochloroaluminate,** $MgCl_2.2AlCl_3$. The corresponding **zinc octodecachlorotetraluminate,** $4AlCl_3.3ZnCl_2$, is a pasty translucent mass, less stable than the preceding compounds, with a negative heat of formation, and a heat of soln. at 15°, 275·98 Cals.

E. Beckmann found that on adding baryta-water in excess to a soln. of aluminium chloride, the precipitated alumina is dissolved, and on evaporating an hydrated **barium**

oxychloroaluminate, $Al_2O_3.BaO.3BaCl_2+Aq.$, crystallizes out in microscopic rhombic crystals. The substance may also be obtained when a cold conc. soln. of the barium aluminate, $Al_2O_3.2BaO+Aq.$, is sat. with barium chloride. Under other conditions, a compound of the formula $Al_2O_3.BaO.BaCl_2$, can be prepared. Similarly, when a current of carbonic anhydride is passed into an aq. soln. of these substances, the aluminium and a portion of the barium is precipitated, only the halogen salt remaining in soln.

§ 16. Aluminium Bromide

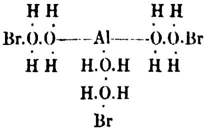
C. Friedel and L. Roux[1] claim to have made aluminium sub-bromide analogous with the corresponding subchloride (*q.v.*). C. Löwig prepared anhydrous aluminium bromide by a process analogous to that employed by H. C. Oersted for the chloride; R. Weber, G. Gustavson, and H. St. C. Deville and L. Troost made it by passing bromine vapour over heated aluminium foil; and they purified the product by redistillation. J. W. Mallet redistilled the aluminium bromide from aluminium in an atm. of nitrogen. The preparation of highly purified aluminium bromide was studied by T. W. Richards and H. Krepelka. I. A. Kablukoff recommends the following process for preparing large quantities of aluminium bromide ·

> The beak of a glass retort is connected with a sloping, hard glass tube heated in a combustion furnace and bent at the lower end so as to fit into a glass receiver. After the retort is charged with aluminium chips and the hard glass tube is heated sufficiently to prevent bromine or aluminium bromide from condensing in it, bromine is allowed to fall gradually on to the aluminium from a tap-funnel, bromine vapour from the receiver being conducted to a draught by means of a tube. After redistillation, the aluminium bromide is obtained as a colourless liquid solidifying to a white mass. Any iron in the aluminium is precipitated according to the reaction: $Fe_2Br_6+2Al=Al_2Br_6+2Fe$.

tha

soln. at 10 Weber, J. B. Berthemot, and C. Löwig made needle-like crystals of **hexa-**
E. Bec**ated aluminium bromide,** $AlBr_3.6H_2O$, by evaporating an aq. soln. of the salt
chloride,t conc. sulphuric acid; or by treating a soln. of aluminium hydroxide in hydro-
acid in a similar manner. According to R. Weber, the crystals when heated

decompose into water, hydrogen bromide, and alumina. J. L. Kreider found that when hexahydrated aluminium bromide is heated between 100° and 210° both water and hydrogen bromide are simultaneously evolved whether the salt be heated in air or in an atm. of hydrogen bromide, but the action in the latter case is retarded. Unlike hexahydrated magnesium bromide, there is no evidence of a differentiation of the water mols. during the dehydration, and he therefore represents this salt by the graphic formula :



$$\begin{array}{ccccc} & \mathrm{H\,H} & & \mathrm{H\,H} & \\ \mathrm{Br.} & \dot{\mathrm{O}}.\dot{\mathrm{O}} & \text{———}\mathrm{Al}\text{———} & \dot{\mathrm{O}}.\dot{\mathrm{O}} & \mathrm{.Br} \\ & \mathrm{H\,H} & \mathrm{H.\dot{O}.H} & \mathrm{H\,H} & \\ & & \mathrm{H.\dot{O}.H} & & \\ & & \mathrm{\dot{Br}} & & \end{array}$$

On cooling a 46 per cent. soln. of aluminium bromide by means of a calcium chloride freezing mixture, after some under cooling, crystallization occurs with a rise of temp. to −9°. The crystals are employed for inoculating a somewhat dil. soln. of aluminium bromide and a mass of colourless needle-like crystals of **pentadecahydrated aluminium bromide,** $AlBr_3.15H_2O$, are obtained. They are dried by press. between filter paper ; they melt at −7·5°, forming a turbid liquid at −5°, which becomes clear at 0°, and decomposes at 7°.

Anhydrous aluminium bromide forms lustrous rhombohedral plates of sp. gr. 2·54. R. Weber found the crystals melt at about 90° to a colourless mobile liquid which boils between 265° and 270°. W. Biltz and co-workers gave 3·01 for the sp. gr. at 25°/4°, and 88·7 for the mol. vol. ; and W. Biltz and A. Voigt found the sp. gr. at different temp. to be

	100°	125°	150°	175°	200°	225°	265°
Sp. gr. .	2·64	2·57	2·52	2·46	2·40	2·35	2·26

The coeff. of thermal expansion is 0·001. J. W. Mallet says the m.p. is 93°, and the b p. 263·3° at 747 mm. press. L. Rotinjanz and W. Suchodsky give 772° K. for the critical temp., and the absolute boiling temp. 533° K., so that the ratio $T_b/T_c=0·690$. According to H. St. C. Deville, the vapour density is 18·62 at 444° in agreement with 18·5, the theoretical value for Al_2Br_6. I. A. Kablukoff gives 0·08912 for the sp. ht. of aluminium bromide between 22° and 76° ; for the latent heat of fusion 10·47 cals. per gram ; and for the mol. depression of the f.p., 262°. E. P. Kohler found the effect of this salt on the b.p. of carbon disulphide and nitrobenzene agreed with the formula Al_2Br_6 : E. Beckmann also obtained a similar result with boiling soln. in bromine, and by the f.p. method. W. Biltz found the effect on the f.p. of water agreed with the formula Al_2Br_6, or possibly with the ionization of the complex $Al[AlBr_6] \rightleftharpoons Al^{\cdots} + AlBr_6'''$. W. Finkelstein found the mol. wt. from the f.p. of aluminium bromide in bromine corresponds with Al_2Br_6 for all conc. The soln. is an electrical conductor. M. Prud'homme, and E. van Aubel discussed the relation between the m.p., the b.p., and the critical temp. J. Thomsen gave for the heat of formation (Al, Br_3) = 120 Cals., M. Berthelot, 126 Cals. ; and N. N. Beketoff, 123 Cals.; G. Gustavson gives for the heat of soln., 90·118 Cals. As in the case of aluminium bromide, W. Hampe says that molten aluminium bromide is a non-conductor of electricity if heated up to its b.p. provided the salt be of a high degree of purity. W. Biltz and A. Voigt found the conductivity curve of aluminium bromide was similar to that of the chloride, Fig. 60,

	195°	232°	260°	266°	270°
Mho × 10^7 . .	0·90	1·6	2·0	2·4	2·6

According to W. A. Isobekoff, and W. A. Plotnikoff, soln. of the halogen salts in fused aluminium bromide are conductors.

M. Berthelot found that water reacts with aluminium bromide with explosive violence, R. Weber said that it decomposes when heated in air, and M. Berthelot added that when heated to dull redness in oxygen, it burns to alumina. W. A. Plotnikoff found soln. of aluminium bromide in ethyl bromide conduct the electric current more feebly than aq. soln.; and that the mol. conductivity of normal soln. in ethyl bromide is three times as great as a $\frac{1}{10}N$-soln. Aluminium appears on the cathode during the electrolysis of these solns. H. E. Patten found the metal attacks the solvent, forming butane: $2Al+6C_2H_5Br=2AlBr_3+3C_4H_{10}$. R. Weber found aluminium bromide to dissolve in carbon disulphide, and that the soln. fumes strongly in air. W. Eidmann found it to be soluble in acetone. Like aluminium chloride, this salt was found by R. Weber and W. A. Plotnikoff to form a white compound, $AlBr_3.H_2S$, with hydrogen sulphide, melting at 84°.

According to R. Weber, aluminium bromide absorbs ammonia at ordinary temp. The speed of absorption is at first slow, and then rapid; the product swells up and forms a voluminous powder of **aluminium amminobromide** which loses ammonia when exposed to the air or when warmed. The ammino-compound can be sublimed in a sealed tube without melting; and when treated with water, ammonia is evolved and aluminium hydroxide is formed. W. A. Plotnikoff obtained with phosphoryl chloride a compound which has the formula $2AlBr_3.2POCl_3$ in a soln. of carbon disulphide; W. A. Plotnikoff has described the compound $AlBr_3.Br_4.CS_2$ as a result of the action of bromine on a soln. of aluminium bromide in carbon disulphide. It melts in a sealed tube at 86°-90°, and it decomposes at a higher temp.; it is reddened in sunlight or by moisture; it is soluble in many organic liquids; and is converted by water into C. Hell and F. Urech's *trithiobromide*, $C_2Br_6S_3$. W. A. Plotnikoff also prepared complexes with phosphorus tribromide and ethyl bromide, $AlBr_3.PBr_3.C_2H_5Br$, ethylidene bromide, etc., may be substituted for ethyl bromide; similarly with phosphorus pentabromide, $AlBr_3.PBr_5.C_2H_5Br$.

Aluminium bromide reacts with carbonyl chloride, forming aluminium chloride: $AlBr_3+3COCl_2=AlCl_3+3COClBr$, provided the carbonyl chloride be in excess, while if the aluminium bromide be in excess, **aluminium dichlorobromide,** $AlBrCl_2$, is formed. A. von Bartal prepared the last-named compound by passing carbonyl chloride into aluminium bromide in a flask heated in a water-bath and connected with a second flask placed in a freezing mixture until the contents of the first flask became solid. The distillate in the second flask consisted mainly of bromine with some carbonyl bromide. From part of the solid residue in the first flask, anhydrous aluminium chlorobromide was obtained, by sublimation in a vacuum, as small, brick-red leaflets which fume and deliquesce in the air. The compound sublimes practically unchanged at 100°-120°/15-20 mm., and melts when heated at 142°-143° in a sealed tube. Another portion of the solid residue was dissolved in ice-cold water, and on careful evaporation **hexahydrated aluminium dichlorobromide,** $AlCl_2Br\,6H_2O$, was obtained in small, light red to yellow crystals. The hydroxide does not fume in the air, but is deliquescent and easily soluble in water; it does not melt even when heated in a sealed tube, but at higher temp. loses water and decomposes.

J. Kendall and co-workers prepared **ammonium tetrabromoaluminate,** $NH_4Br.AlBr_3$, melting at 232°; **ammonium heptabromoaluminate,** $NH_4Br.2AlBr_3$, melting at 104·2°; **ammonium decabromoaluminate,** $NH_4Br.3AlBr_3$, melting at 97·8°; **lithium tetrabromoaluminate,** $LiBr.AlBr_3$, melting at 197°; **lithium heptabromoaluminate,** $LiBr.2AlBr_3$, melting at 197°; **lithium docosibromoaluminate,** $LiBr.7AlBr_3$, melting at 114·8°; **sodium tetrabromoaluminate,** $NaBr.AlBr_3$, melting at 201°; **sodium heptabromoaluminate,** $NaBr.2AlBr_3$; and **sodium tricosibromoaluminate,** $2NaBr.7AlBr_3$, melting at 95·6°. R. Weber prepared what he regarded as a double salt, **potassium tetrabromoaluminate,** $AlBr_3.KBr$, by fusing together the component salts. J. Kendall made the same salt, melting at 191·5°; **potassium heptabromoaluminate,** $KBr.2AlBr_3$, melting at 95·8°; **silver tetrabromoaluminate,** $AgBr.AlBr_3$, melting at 215·6°; **silver heptabromoaluminate,** $AgBr.2AlBr_3$; **calcium octobromoaluminate,** $CaBr_2.2AlBr_3$, melting at 306°; and **barium octobromoaluminate,** $BaBr_2.2AlBr_3$. E. Beckmann also made **barium oxybromoaluminate,**

$Al_2O_3.BaO.BaBr_2.Aq.$, analogous to the corresponding chloride. J. Kendall and co-workers made **magnesium octobromoaluminate,** $MgBr_2.2AlBr_3$; **zinc octobromoaluminate,** $ZnBr_2.2AlBr_3$, melting at 111·5°; **cadmium octobromoaluminate,** $CdBr_2.2AlBr_3$, melting at 224°; **mercurous tetrabromoaluminate,** $HgBr.AlBr_3$, melting at 261°; and two forms of **mercuric octobromoaluminate,** $HgBr_2.2AlBr_3$, melting respectively at 102·8° and 103·9°. M. I. Konowaloff, W. A. Plotnikoff, G. Gustavson, and others have studied the compounds of aluminium chloride with various organic compounds. G. Gustavson, and J. A. Besson used aluminium bromide as a brominating agent in organic synthesis.

§ 17. Aluminium Iodide

According to F. Wohler,[1] aluminium does not alter when heated in iodine vapour, but R. Weber found that if heated with about ten times its weight of iodine in a sealed tube the combination was attended by the evolution of light and heat. The brown product can be purified by repeated sublimation with an excess of aluminium in a sealed tube. R. Weber also formed the same compound by heating aluminium with silver iodide in a sealed tube. G. Gustavson heated the two elements in a stream of dry carbon dioxide and obtained aluminium iodide; and he obtained the same compound by leaving a mixture of eq. proportions of the two elements and three times their weight of carbon disulphide in a stoppered vessel for about two days at the ordinary temp. The iodide dissolves in the solvent as fast as it is formed. The action is slower with benzene or ethyl iodide as solvent. I. L. Panfiloff made an aq. soln. by digesting aluminium with iodine in the presence of warm water, and R. Weber by dissolving aluminium hydroxide in hydriodic acid.

By evaporating an aq. soln. of aluminium iodide over conc. sulphuric acid, R. Weber obtained yellowish or white crystals of **hexahydrated aluminium iodide,** $AlI_3.6H_2O$, which, when heated, give off water, iodine, and hydrogen iodide, leaving residual alumina. I. L. Panfiloff treated a 58 per cent. soln. of aluminium iodide as in the case of aluminium bromide, and obtained yellowish or white needles of **pentadecahydrated aluminium iodide,** $AlI_3.15H_2O$, which begin to melt at −25° and are completely fluid at −18°. F. Ephraim and I. Kornblum made **aluminium sulphitoiodide,** $AlI_3.SO_2$, by direct union of the constituents at a low temp.

Anhydrous aluminium iodide forms white deliquescent plates which can be purified by crystallization from carbon disulphide. The crystals have a sp. gr. of 2·63, and melt to a mobile liquid at 185°. W. Biltz and co-workers gave 3·98 for the sp. gr. at 25°/4°, and 102·5 for the mol. vol. W. Biltz and A. Voigt found

	200°	205°	210°	220°	230°	240°	382°
Sp. gr. . . .	3·20	3·18	3·17	3·15	3·12	3·10	2·78

According to L. Rotinjanz and W. Suchodsky, aluminium iodide boils at 350° or 623° K., and has a critical temp. of 955° K., so that the ratio $T_b/T_c=0·652$. H. St. C. Deville and L. Troost found the vapour density at 444° to be 27·0 (air unity) when the theoretical value for the formula Al_2I_6 is 28·2. E. Beckmann found the mol. wt. of a soln. of aluminium iodide in molten iodine agrees with the formula Al_2I_6; and E. P. Kohler obtained a similar result for soln. in boiling carbon disulphide. M. Prud'homme, and E. van Aubel discussed the relation between the m.p., the b.p., and the critical temp. The heat of formation is 86·3 Cals., according to M. Berthelot; J. Thomsen gives 70·3 Cals. and the heat of soln. 89 cals. W. Biltz and A. Voigt found the electrical conductivity curve to be general like that of aluminium chloride, Fig. 61,

	200°	226°	238°	260°	270°
Mho × 10^6	2·6	3·9	4·7	6·3	7·4

According to R. Weber, aluminium iodide decomposes very easily when heated in air, losing iodine and forming alumina; the vapour of aluminium iodide is inflammable, burning with an orange-red flame, forming a cloud of alumina; and M. Berthelot found a mixture of the vapour of aluminium iodide and air explodes in contact with a flame, and he explains this by the difference in the heats of formation—Al_2I_6, 172·6 Cals.; Al_2O_3, 391·6 Cals. Aluminium iodide fumes in air, and deliquesces rapidly. It readily dissolves in water with the evolution of much heat; when the aq. soln. is boiled, it decomposes, as also is the case with aq. or alcoholic soln. in the presence of zinc or aluminium. According to R. Weber, hydrogen sulphide has no action on aluminium iodide.

According to R. Weber, aluminium iodide does not absorb ammonia, but E. C. Franklin finds it to be very soluble in liquid ammonia, forming a clear colourless soln. from which **aluminium icosiamminoiodide,** $AlI_3.20NH_3$, crystallizes on cooling to −33°; at 8° to 13°, these crystals lose ammonia, and form **aluminium hexamminoiodide,** $AlI_3.6NH_3$. Considerable quantities of potassium amide, KNH_2, can be added to the soln. of aluminium iodide in liquid ammonia without forming a permanent precipitate, for the precipitate which first appears dissolves when the liquid is agitated. With limited amounts of potassium iodide, aluminium triiodotriamide, $Al_2(NH_2)_3I_3$, or $AlI_3.Al(NH_2)_3$, is formed: $3KNH_2+2AlI_3=3KI+AlI_3.Al(NH_2)_3$. At ordinary temp., this salt separates from its soln. with six mols. of ammonia of crystallization forming **aluminium hexamminotriiodotriamide,** $Al(NH_2)_3.AlI_3.6NH_3$; at low temp. the salt separates with about twenty mols. of ammonia of crystallization, and when treated with potassium amide this compound produces insoluble **aluminium amminoiodopentamide,** $Al_2(NH_2)_5I.NH_3$, or $Al(NH_2)_3.Al(NH_2)_2I.NH_3$, which, when heated to 160°, loses two mols. of ammonia, producing **aluminium iodoimidotriamide,** $Al(NH_2)_3.AlNHI$. The salt is soluble in carbon disulphide, from which it crystallizes when a hot soln. is cooled; it is also soluble in alcohol; and, according to G. Gustavson, in ether. Carbon tetrachloride, CCl_4, and hexachloride, C_2Cl_6, react vigorously with the liberation of iodine, and G. Gustavson represents the reaction in a soln. of carbon disulphide: $4AlI_3+3CCl_4=3CI_4+4AlCl_3$. A. von Bartal found liquid carbonyl chloride reacts vigorously with aluminium iodide dissolved in carbon disulphide, but no new compounds were isolated from the products—*vide* the corresponding reaction with aluminium bromide.

R. Weber heated powdered potassium iodide with aluminium iodide in a sealed tube and obtained a crystalline mass of **potassium tetraiodoaluminate,** $AlI_3.KI$, or $KAlI_4$, which melts readily, and is not easily decomposed at high temp. It dissolves in water with the evolution of much heat. Similar remarks apply to **sodium tetraiodoaluminate,** $NaAlI_4$. E. Beckmann prepared **barium oxyiodoaluminate,** $Al_2O_3.BaO.BaI_24Aq.$, analogous to the corresponding chloride. A. Duboin alternately dissolved aluminium and mercuric iodides in water until saturated and obtained a clear yellow liquid, $D^{20\cdot1}$ 3·05, which, when placed in dry air for several months, absorbs oxygen, becoming much deeper in colour, and depositing crystals of the **mercuric oxyiodoaluminate,** $HgO.2AlI_3.3HgI_2.15H_2O$, having D° 3·97. A soln. of aluminium iodide dissolves silver iodide, giving a liquid, $D^{19\cdot8}$ 2·34. This, on spontaneous evaporation, deposits yellow crystals of **silver oxyiodoaluminate :** $2AlI_3.5AgI.2AgO.13H_2O$, which alter extremely rapidly in air.

§ 18. Aluminium Sulphides

F. Wohler[1] distilled sulphur over aluminium without combination, but, according to F. G. Reichel, if sulphur vapour be carried in a stream of hydrogen over red-hot aluminium, or, according to F. Wöhler, if sulphur be thrown into red-hot aluminium, a vigorous reaction ensues, and **aluminium sulphide,** Al_2S_3, is formed. F. Knapp and P. Ebell obtained it by adding sulphur to molten aluminium. W. Spring said that a little sulphide is formed when a mixture of sulphur and aluminium is compressed at 65 atm. W. Stein obtained aluminium sulphide by burning aluminium in sulphur vapour ; and H. Fonzes-Diacon, by igniting a mixture of sulphur and fine aluminium powder by means of a piece of burning magnesium. The combustion is propagated through the mass ; C. Matignon prepared it in a similar manner. W. Biltz and F. Caspari purified the product by sublimation in vacuo at 1100°–1250°, when it forms crystals resembling asbestos. Good crystals are obtained by sublimation, in nitrogen under atm. press., from a carbon tube at 1500°–1600°. The yellow sublimate, more volatile than aluminium sulphide, is silicon sulphide.

H. St. C. Deville said that neither hydrogen sulphide nor potassium sulphide acts on red-hot aluminium, and F. G. Reichel made a similar observation with respect to ammonium sulphide. Aluminium, however, reacts readily with many other sulphides, forming aluminium sulphide and an alloy of the metal and aluminium. H. Fonzes-Diacon ignited a mixture of aluminium powder and antimony sulphide by means of a piece of burning magnesium, the combustion is rapidly propagated through the mass ; A. Mourlot heated aluminium with an excess of antimony sulphide in an electric furnace, the antimony volatilized, and crystalline aluminium sulphide remained. A. Mourlot also used a mixture of aluminium and zinc sulphide ; C. Tissier, silver sulphide ; and C. T. J. Vautin, lead or other metal sulphide.

According to F. G. Reichel, a mixture of alumina and sulphur or sulphur and carbon does not furnish aluminium sulphide, but A. H. Bucherer obtained the sulphide by the action of sulphur on a white-hot mixture of alumina and carbon. C. W. Vincent obtained the sulphide by heating alumina with sodium sulphide; W. Stein, by heating alumina with sodium carbonate and sulphur; and T. Petitjean, and M. Herzog, by heating alumina with soda, sulphur, and tar. O. Schumann found that traces only of aluminium sulphide are formed when hydrogen sulphide is passed over red-hot alumina. A. Gautier found hydrogen sulphide furnishes *aluminium oxysulphide* $Al_2O_3.Al_2S_3$, when passed over alumina at a white heat, $4Al_2O_3+9H_2S=2(Al_2O_3.Al_2S_3)+3SO_2+9H_2$. E. Frémy showed that if carbon disulphide be employed, aluminium sulphide is readily formed. E. Frémy said:

> It is well known that sulphur has no action on alumina. I thought it might be possible to replace the oxygen by sulphur if I introduced or intervened a second affinity as that of carbon for oxygen. Decompositions produced by two affinities are very frequent in chemistry; it is thus that carbon and chlorine, by acting simultaneously on silica or alumina, produce silicon or aluminium chloride, while either alone could not decompose it. . . . I thought that carbon disulphide ought to act at a high temp. on silica, magnesia, and alumina producing easily their sulphides. Experiment confirmed this view. . . . To facilitate the reaction with alumina, and to protect the sulphide from the decomposing action of the alkalies contained in the porcelain tube which was used, I found it sometimes useful to mix the oxides with carbon and to form the mixture into bullets resembling those employed in the preparation of aluminium chloride. I ordinarily placed the bullets in little carbon boats, and heated the tube to whiteness in the current of vaporized carbon bisulphide. The presence of divided carbon does not appear useful in the preparation of this sulphide. Aluminium sulphide being non-volatile (under these conditions) it is always mixed with some about 63·5 per cent. undecomposed alumina. Indeed, it is impossible to transform entirely all the alumina into sulphide.

W. Stein used a similar process, but H. N. Warren failed to obtain sulphide either at a red or at a white heat. L. P. B. E. Cumenge made the carbon disulphide at one end of the same retort as the aluminium sulphide was made. D. G. Reillon, S. C. Montague, and O. L. B. L. Bourgerel passed carbon disulphide into a red-hot mixture of alumina and carbon: $2Al_2O_3+3C+3CS_2=2Al_2S_3+6CO$. D. A. Peniakoff prepared aluminium sulphide by heating aluminium sulphate, phosphate, manganate, or chromate with carbon disulphide, or carbonyl sulphide: $Al_2(SO_4)_3+6CS_2=Al_2S_3+6CO_2+12S$; and $2AlPO_4+4CS_2=Al_2S_3+P_2S_5+4CO_2$. O. Schumann did not succeed in reducing aluminium sulphate to the sulphide by heating it in a current of hydrogen, but A. Violi reduced the sulphate by heating it with sulphur. D. A. Peniakoff said that when the aluminium halides, or alkali aluminium halides, are fused with sodium sulphide, aluminium sulphide is obtained in a form suitable for reduction to aluminium: $2AlF_3+3Na_2S=Al_2S_3+6NaF$; $2Na_3AlF_6+3Na_2S=Al_2S_3+12NaF$. According to F. Lauterborn, aluminium sulphide is formed by heating a mixture of alumina and calcium sulphide. H. S. Blackmore heated a soln. of alumina in molten alkali fluoride, chloride, or aluminate in a stream of carbon disulphide. T. R. Haglund heated alumina, coal and carbides, and a sulphur compound.

F. Wöhler's sulphide prepared in 1829 was a black, vitreous mass; E. Frémy's, prepared 24 years later, was also a vitreous mass; A. Mourlot's was a crystalline mass. W. Biltz and F. Caspari's product, purified by sublimation, forms long, white, hexagonal, needle-like crystals with a sp. gr. 2·02 at 13°/13°—A. Mourlot gave 2·37. W. Biltz and F. Caspari found the m.p. to be 1100°±10°; and mixtures with alumina melted at a lower temp. and formed solid soln. A mixture of the sulphide with 27 per cent. of oxide melted at 997°. P. Sabatier gave for the heat of formation (2Al, 3S)=124·4 Cals., and for the heat of decomposition with water at 12°, Al_2S_3+Aq., 74 Cals.

F. Wöhler noted that when aluminium sulphide is exposed to air, it gradually swells up emitting hydrogen sulphide, and finally crumbling to a greyish-white powder. In accord with the fact that aluminium sulphide is a salt of a very weak acid, and of a very weak, practically insoluble base, water hydrolyzes the sulphide into aluminium hydroxide and hydrosulphuric acid: $Al_2S_3+6H_2O=3H_2S+2Al(OH)_3$, probably, added W. Biltz and F. Caspari, with the formation of intermediate compounds, since the prolonged action of moist hydrogen sulphide gives the oxysulphide $Al_2O_3.Al_2S_3.H_2O$. The action of water on aluminium sulphide has been proposed as a very convenient means of generating hydrogen sulphide. The hydrolysis by warm water is turbulent. A. Mourlot said the crystalline sulphide is not attacked by water so rapidly as the amorphous sulphide. According to E. Frémy, aluminium sulphide at a red heat is decomposed by steam; and crystals of corundum are formed. P. Curie said that hydrochloric acid furnishes the chloride and hydrogen sulphide. M. Houdard said that when heated in the electric furnace, aluminium sulphide, mixed with carbon, is not volatilized or transformed into carbide nor does it dissolve any carbon. H. C. Geelmuyden said that aluminium sulphide is not reduced by calcium carbide. F. G. Reichel said that iron and copper decompose aluminium sulphide at a red heat; and T. Petitjean said that iron and hydrocarbons reduce it to aluminium. The reduction of aluminium sulphide has been suggested as a convenient means of preparing the metal (*q.v.*). M. Houdard noted that alumina is soluble in fused aluminium sulphide, and crystallizes as corundum on cooling.

F. F. Regelsberger melted alumina with sulphur in an electric furnace, and obtained a product with about 90 per cent. of what he regarded as **aluminium subsulphide,** AlS. which loses hydrogen sulphide when exposed to atm. air, and is decomposed by water, acids, or alkalies with the evolution of hydrogen and hydrogen sulphide: $2AlS+6HCl=2AlCl_3+2H_2S+H_2$. W. Biltz and F. Caspari obtained the sub-sulphide by heating the ordinary sulphide to 2100° in an atm. of an inert gas.

D. A. Peniakoff obtained complex sulphides by heating aluminium sulphate or phosphate with a sulphide of the alkalies, alkaline earths, zinc, or manganese in a stream of carbon disulphide, $2Al_2O_3+4R'_3PO_4+11CS_2=2(Al_2S_3.3R'_2S)+2P_2S_5+11CO_2$; and with the sulphate, $Al_2(SO_4)_3+3R''S+6S=Al_2S_3.3R''S+6SO_2$. M. M. Jännigen prepared **sodium sulphoaluminate,** $Na_6Al_2S_6$, or $Al_2S_3.3Na_2S$, by heating aluminium oxide with sodium carbonate in an atm. of carbon disulphide; and he made **potassium sulphoaluminate,** $K_6Al_2S_6$, or $Al_2S_3.3K_2S$, in a similar manner. H. St. C. Deville described a complex sulphide of aluminium and potassium obtained by passing sulphur vapour over a strongly ignited mixture of carbon with potash-alum. The product was said to decompose water with violence. D. Gratama repeated the work and obtained a product which was spontaneously inflammable; yielding no gas with water, and only a slight evolution of hydrogen sulphide when treated with hydrochloric acid. The filtered soln. contained no aluminium. No double sulphide was formed.

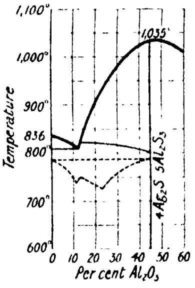

FIG. 62.—Freezing-point Curves of Silver and Aluminium Sulphides.

H. Ditz thought it possible that *copper sulphoaluminate* is formed by the action of aluminium on cupric sulphide. L. Cambi investigated the system $Ag_2S-Al_2S_3$ by thermal analysis. His results are summarized in Fig. 62 so far as mixtures containing 40 molar per cent. of aluminium sulphide are concerned. There is evidence of the formation of **silver enneadecasulphodecaluminate,** $4Ag_2S.5Al_2S_3$, or $Ag_8Al_{10}S_{19}$, which melts unchanged at 1038°, and forms homogeneous, flesh-coloured, birefringent crystals. There is also evidence of the formation of a second compound, decomposing at 825°, very near the eutectic, and containing 60 to 70 molar per cent. of silver sulphide. M. M. Jännigen reported the formation of **calcium, strontium, and barium sulphoaluminates** by the process he used for the sodium salt. D. A. Peniakoff made these salts by the process indicated above.

M. Houdard heated a mixture of one gram-atom of magnesium and two gram-atoms of aluminium in a stream of carbon disulphide, and obtained a crystalline mass of **magnesium sulphoaluminate**, $MgS.Al_2S_3$, analogous in crystalline form to spinel. The compound is decomposed by oxygen-free water, by 90 per cent. alcohol, and by acetic acid diluted with alcohol. D. A. Peniakoff made *zinc sulphoaluminate* as indicated above.

§ 19. Aluminium Sulphates

Technical processes for preparing aluminium sulphate from clay, bauxite, etc. have been previously described,[1] or are indicated in connection with alum. This salt is obtained in soln. by dissolving aluminium hydroxide in sulphuric acid. H. V. Collet-Descotils boiled ammonia alum with aqua regia until all the ammonia was destroyed. The soln. does not crystallize readily. J. Bock recommended concentrating the soln. in vacuo until crystals are formed, and more soln. added from time to time, which results in the production of very large crystals. The Norske Aktieselskab for Elektrokem. Ind. electrolyzed a soln. of aluminium sulphate containing a little sodium sulphate in a diaphragm cell at 60° 80°; the free acid developed in the anode compartment dissolved the raw material labradorite in the anode compartment, and thus aluminium sulphate is extracted from that felspar. Basic aluminium sulphate deposits on the anode. J. Morel made aluminium sulphate by heating bauxite with a mixture of air, steam, and sulphur dioxide at a temp. not exceeding 800°. W. Fulda heated aluminium hydroxide with ammonium sulphate, and reconverted the ammonia to sulphate by the gypsum process; and he later recommended ammonia-alum in place of ammonium sulphate.

H. von Kéler and G. Lunge found in commercial aluminium sulphate 0·00050 to 0·0054 per cent. of iron presumably present as ferric sulphate; 0·53 to 1·05 per cent. of free sulphuric acid; and in one sample they found 0·00156 per cent. of zinc. F. Wirth and B. Bakke[2] were unable to separate ferric sulphate from aluminium sulphate by crystallization, but it is possible to do so if the ferric salt be reduced to ferrous sulphate by hydrogen sulphide, sulphur dioxide, etc. Arsenic, and alkali sulphates are often present. C. F. Mohr found that the commercial salt is usually contaminated with a little alum. M. Müller described the manufacture of an impure aluminium sulphate suitable as a precipitating agent in sizing paper.

There are some different statements as to the water of crystallization. P. M. Delacharlonny holds that the crystals are normally the **hexadecahydrated**

aluminium sulphate, $Al_2(SO_4)_3.16H_2O$, and the assumption that the salt is octodecahydrated is based on analyses of samples containing ferric sulphate; he also says that samples of native sulphate from Rio Saldana and Bolivia have the composition $Al_2(SO_4)_3.16H_2O$. On the other hand, analyses of J. B. J. D. Boussingault, F. Varrentrapp, E. Lenssen, C. F. Rammelsberg, T. J. Herapath, C. Hartwall, H. Rose, F. Field, J. Jurasky, P. Zellner, L. Barth, etc., show that the salt is **octodecahydrated aluminium sulphate,** $Al_2(SO_4)_3.18H_2O$. R. J. Kane said that the octodecahydrate crystallizes from its soln. in hydrochloric acid in beautiful tabular crystals. The mineral *alunogen* is also an octodecahydrate of the normal sulphate. The hybrid term *alunogene* was first applied by F. S. Beudant; N. Mill used *davite*; E. F. Glocker, *keramohalite* and *stypterite*; J. J. N. Huot, *saldanite*; C. U. Shepard, *solfatarite*; and J. F. Hausmann, *halotrichite*. The native sulphate is found as a product of volcanic action and as a product of the decomposition of pyrites and alum shales. B. Boutzoureano reported the formation of **trihydrated aluminium sulphate,** $Al_2(SO_4)_3.3H_2O$, in regular tetrahedral crystals. O. Schmatolla said that **hexahydrated aluminium sulphate,** $Al_2(SO_4)_3.6H_2O$, is formed as a white powder when aluminium sulphate is heated for a long time with conc. sulphuric acid, washed with ice-cold water, and dried at 100°. C. von Hauer precipitated what he regarded as **decahydrated aluminium sulphate,** $Al_2(SO_4)_3.10H_2O$, in tabular crystals, by adding alcohol to a dil. aq. soln. of the sulphate. Both these hydrates are said to form the octodecahydrate on exposure to a moist atm. A. Gawalowsky said that **heptadecahydrated aluminium sulphate,** $Al_2(SO_4)_3.17H_2O$, is obtained from the soln. produced by incompletely saturating sulphuric acid with gelatinous aluminium hydroxide. E. Metzger said that **heptacosihydrated aluminium sulphate,** $Al_2(SO_4)_3.27H_2O$, is formed when a sat. aq. soln. of aluminium sulphate is exposed to a winter's cold; or if the ordinary hydrate is made into a mush with water and cooled below 9·5°.

A. B. Poggiale measured the **solubility** of aluminium sulphate in water between 0° and 100°. Expressing the results in grams $Al_2(SO_4)_3$ per 100 grms. of sat. soln.

	0°	10°	20°	40°	60°	80°	100°
Solubility . .	23·8	25·1	26·7	31·4	37·2	42·2	47·1

The solid phase over the whole range is $Al_2(SO_4)_3.18H_2O$. R. Kremann and K. Huttinger explored the system at still lower temp. with the idea of finding what hydrates exist at these temp. The octodecahydrate is the solid phase down to the eutectic at −4°. Expressing the results as before:

	−1·02°	−1·43°	−2·04°	−2·65°	−2·85°	−4°	7·73°
Solubility . .	8·09	10·7	14·3	17·5	19·2	23·1	24·8
Solid phase . .	Ice					18-hydrate	

These results are plotted in Fig. 63. R. Kremann and K. Hüttinger also measured

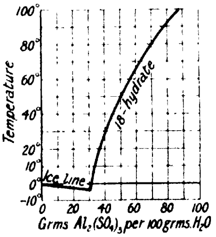

FIG. 63.—Solubility of Aluminium Sulphate in Water.

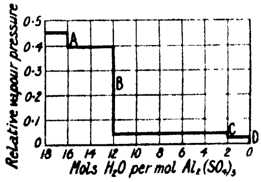

FIG. 64.—Relative Vapour Pressure of the Hydrates of Aluminium Sulphate.

the **vapour pressure** while the water is being gradually withdrawn, and they found breaks in the curve, Fig. 64, corresponding with *A*, the passage from the octodeca- to the hexadecahydrate; the passage from the hexadecahydrate to **dodecahydrated**

aluminium sulphate, $Al_2(SO_4)_3.12H_2O$; *C*, the passage from the dodecahydrate to **dihydrated aluminium sulphate,** $Al_2(SO_4)_3.2H_2O$; and *D*, the passage from the dihydrate to the anhydrous salt. This, of course, assumes that basic sulphates are not formed during the dehydration of the octodecahydrate.

According to C. J. B. Karsten, when hydrated aluminium sulphate is heated, it first melts in its water of crystallization, intumesces, and finally leaves a white porous mass of the anhydrous sulphate, $Al_2(SO_4)_3$; and, as F. Stromeyer also showed, if heated still further, it loses the whole of its contained sulphur trioxide, without melting. K. Friedrich said that decomposition begins at 770°. L. Wöhler and coworkers found the partial press. of the SO_3 with decomposing aluminium sulphate is :

	580°	620°	660°	680°	700°	720°	740°
Press. SO_3 . . .	20·4	30·2	47·0	54·0	72·2	95·5	154·5 mm.
	572°	621°	681°	702°	720°	742°	748°
Total press. . . .	28	51	120	180	261	480	692 mm.

C. R. Fresenius found that 5-10 mins.' heating over a blast-flame suffices to expel the sulphur trioxide ; but, as F. Varrentrapp showed, a lower temp. is not sufficient to do this ; and F. Stolba found that over the bunsen flame, the residue is eq. to $2Al_2O_3.SO_3$ after 4 hrs.' heating.

The octodecahydrated salt furnishes acicular or lamellar **crystals** ; the mineral occurs in delicate fibrous masses or crusts, and also massive. J. Jurasky said the crystals are monoclinic. A. Gawalowsky obtained smooth tetrahedral crystals with truncated edges. C. F. Rammelsberg said that the heptacosihydrate forms trigonal crystals with axial ratio and angle $a : c = 1 : 1·5408$, and $\alpha = 83° 0'$. The **specific gravity** of the anhydrous sulphate was found by C. J. B. Karsten to be 2·74 ; L. Playfair and J. P. Joule gave 2·171 ; P. A. Favre and C. A. Valson, 2·672 at 22·5° ; and O. Pettersson, 2·713 at 17°. For the octodecahydrate, L. Playfair and J. P. Joule gave 1·671 ; E. Filhol, 1·569 ; P. A. Favre and C. A. Valson, 1·767 at 22·1° ; and J. Dewar, 1·6913 at 17°, and 1·7184 at −188°. According to C. Reuss, the sp. gr. of aq. soln. of purified aluminium sulphate (40 per cent. water), referred to water at 4° unity, are as follow :

Per cent. $Al_2(SO_4)_3$ . .		1	5	10	15	20	25
Sp. gr. at .	15° . .	1·0170	1·0569	1·1071	1·1574	1·2074	1·2572
	25° . .	—	1·0503	1·1022	1·1522	1·2002	1·2483
	35° . .	—	1·0450	1·0960	1·1460	1·1920	1·2407
	45° . .	—	1·0356	1·0850	1·1346	1·1801	1·2295

and with commercial aluminium sulphate containing Al_2O_3, 13·52 ; SO_3, 31·58 ; Fe, 0·33 ; K_2O, 0·93 ; and H_2O, 52·27 per cent. :

Per cent. $Al_2(SO_4)_3$ . .	1	5	10	15	20	25
Sp. gr. at 15° . . .	1·0069	1·0377	1·0730	1·1097	1·1440	1·1798

Measurements were also made by F. Fouqué, H. C. Jones, P. A. Favre and C. A. Valson, W. L. Badger and J. S. France, J. Wagner, H. Sentis, C. Chéneveau, etc. The vap. press. of the sulphur trioxide in the thermal decomposition of anhydrous aluminium sulphate was studied by L. and P. Wöhler and W. Plüddemann. For soln. at 12·5° with *w* per cent. of anhydrous salt, J. G. MacGregor found the sp. gr. $S = S_0 + 0·0092083w$, where S_0 represents the sp. gr. of water at 12·5°, and for *w* up to 2·5 per cent. J. Wagner found the **viscosity** of N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln. of aluminium sulphate at 25°, to be respectively 1·4064, 1·1782, 1·0825, and 1·0381. P. H. Prausnitz measured the osmosis of soln. of aluminium sulphate through membranes with pores of various size. W. L. Badger and J. S. France measured the f.p. and b.p. of soln. of aluminium sulphate of different conc. The f.p. rises from about 30° at a sp. gr. 1·30 to a maximum of 85° at sp. gr. 1·60, and then falls to about 70° at a sp. gr. of 1·80 ; the b.p. increases from 101° at a sp. gr. of 1·30 to 118° at a sp. gr. 1·76. G. Tammann measured the lowering of the **vapour pressure** of water at 100° by aluminium sulphate and found that with 9·92, 23·80, and 40·25 grms. of $Al_2(SO_4)_3$ per 100 grms. of water the vap. press. was lowered respectively 7·2 mm., 20·0 mm., and 51·5 mm. L. F. Nilson and O. Pettersson gave 0·1855 for the **specific heat** of the anhydrous salt between 0° and 100°. J. C. G. de Marignac gave for the sp. ht. of soln. with two-thirds of a mol $Al_2(SO_4)_3$, in 50, 100, and 200 mols of water 0·9041, 0·9465, and 0·9722 respectively, between 21°–53°. According to J. Thomsen, the **heat of formation,** ($2Al$, $3O$, $3SO_3$, aq.)=451·77 Cals.; M. Berthelot gave ($2Al$, $3S$, $12O$, aq.)=879·7 Cals., and for the heat of neutralization, $2Al(OH)_3+3H_2SO_4+Aq.=Al_2(SO_4)_3+Aq.+21$ Cals.; ($Al(OH)_3$, $3HCl$, aq.)=27·4 Cals.; and S. U. Pickering gave ($Al(OH)_3$, $3HF$, aq.)=34·1 Cals. L. Wöhler and co-workers gave 17 Cals. for the heat involved in the loss of a mol of SO_3 from a mol of aluminium sulphate. P. A. Favre and C. A. Valson gave 56·0 Cals. for the **heat of solution** of $Al_2(SO_4)_3.6H_2O$; and 8·2 Cals. for the octodecahydrate. L. and P. Wöhler and W. Plüddemann found 17 cals. for the heat of dissociation of anhydrous aluminium sulphate.

The **electrical conductivity** of aq. soln. of aluminium sulphate was measured by F. Kohlrausch,[3] F. S. Svenson, P. Walden, and H. C. Jones and co-workers. The last-named found for the molecular conductivity, μ, with soln. containing a mol of the salt in v litres of water:

v		4	8	32	128	512	2048	4096
μ	0°	51·9	65·21	89·50	121·87	164·08	222·31	262·35
	25°	92·40	114·44	158·01	219·04	301·01	425·03	514·06
	65°	152·8	185·7	266·2	395·1	594·6	943·0	1221·2

The percentage **degree of ionization,** α, calculated from these data:

v		4	8	32	128	512	2048	4096
α	0°	19·8	24·0	34·1	46·5	62·5	84·7	100·0
	65°	12·5	15·2	21·8	32·4	48·7	72·2	100·0

This is on the assumption that the salt is not hydrolyzed in soln. H. Ley found that the **hydrolysis** is smaller than with soln. of the chloride—*vide infra.* H. C. Jones also calculated the temp. coeff. of the conductivity of these soln. J. F. Daniell and W. A. Miller made some observations on the **transport numbers.**

According to J. J. Berzelius, hydrated aluminium sulphate is permanent in air; actually, the crystals show a marked tendency to effloresce; but if a little ferric sulphate be present, the salt may appear to be hygroscopic. The salt has a highly acid taste. According to F. Wöhler, when aluminium sulphate is heated in a stream of **hydrogen,** it furnishes alumina, which, according to O. Schumann, is almost free from sulphate. For the action of **water,** *vide infra,* basic salts. R. Willstätter prepared an aluminium sulphate with **hydrogen peroxide** of crystallization. H. Rose found that when repeatedly calcined with **ammonium chloride,** the aluminium is almost wholly volatilized presumably by being first converted into chloride; and A. B. Prescott found that when evaporated with an excess of **hydrochloric acid,** about 10 per cent. passes into aluminium chloride. A. Recoura boiled aluminium sulphate with hydrochloric acid, and on cooling the soln. obtained a crystalline deposit which he regarded as **aluminium chlorosulphate,** $Al(SO_4)Cl$. According to C. J. B. Karsten, and F. J. Knapp, a conc. soln. of aluminium sulphate can be mixed with **sodium chloride** without any separation, and on evaporation some sodium sulphate and aluminium chloride are formed; and, according to G. Friedel, with **calcium chloride,** some calcium sulphate is produced. A. Cossa found that when aluminium sulphate is heated with **magnesium fluoride,** some magnesium sulphate is formed. According to S. E. Moody, a mixture of **potassium iodide and iodate** reacts with a soln. of aluminium sulphate, forming a basic salt which when boiled is completely hydrolyzed $Al_2(SO_4)_3+5KI+KIO_3+3H_2O=2Al(OH)_3+3K_2SO_4+3I_2$; F. A. Gooch and R. W. Osborne found that the reaction is about five-sixths completed with a mixture of **potassium bromide and bromate;** and very much less with a mixture of **potassium chloride and chlorate.** A. Violi found that aluminium sulphide is formed by fusing the sulphate with **sulphur.** According to A. Seyewetz and

G. Chicandard, **sodium thiosulphate** reacts with aluminium sulphate, $Al_2(SO_4)_3+3Na_2S_2O_3=Al_2O_3+3Na_2SO_4+3SO_2+3S$, in boiling soln., and in the cold, $Al_2(SO_4)_3+3Na_2S_2O_3=3Na_2SO_4+Al_2(S_2O_3)_3$, and the latter then decomposes $Al_2(S_2O_3)_3+3H_2O=3H_2S+Al_2(SO_4)_3$. According to A. d'Heureuse, **iron,** or **zinc** has only a slight action when calcined with aluminium sulphate. F. Kunheim studied the action of **carbon** on aluminium sulphate in the electric arc furnace. J. J. Berzelius reported that hydrated aluminium sulphate is scarcely soluble in **alcohol**; and W. F. O. de Coninck found that 100 grms. of **glycol** dissolve 16·82 grms. of aluminium sulphate.

Acid aluminium sulphates.—The solubility of aluminium sulphate in sulphuric acid has been measured by F. Wirth who found that at 25°, the solid phase was the octodecahydrate, and expressing the results in grams per 100 grms. of sat. soln.,

H_2SO_4 . .	0	5	10	20	30	40	50	60	70	75
$Al_2(SO_4)_3$.	27·8	29·2	26·2	19·5	11·6	4·8	1·5	1·0	2·3	4·0

The presence of sulphuric acid at first raises the solubility of aluminium sulphate in water, but a further increase in the amount of the acid depresses the solubility very considerably; from 20*N*-acid onwards there is a slight increase in solubility without any change in the solid phase.

Three acid aluminium sulphates have been reported:

$$(HSO_4)_2-Al_2(SO_4)_2 \qquad (HSO_4)_4Al_2=SO_4 \qquad (HSO_4)_4Al_2-(HSO_4)_2$$

These salts can also be regarded as *hydrosulphato-aluminic acids;* the salts of the first member forming the class of salts called *alums.* E. Baud found that when aluminium hydroxide or bauxite is boiled with dil. sulphuric acid (1 : 1), **trihydrated aluminium dihydrosulphate,** $Al_2(SO_4)_3.H_2SO_4.3H_2O$, or $Al_2(SO_4)_2(HSO_4)_2.3H_2O$, is formed, and it crystallizes in colourless needles which, after washing with acetone, can be dried on a porous tile. The salt is also formed when aluminium sulphate is dissolved in sulphuric acid at 110°–112°; and, according to F. Wirth, a mixture of conc. sulphuric acid and aluminium sulphate solidifies in a few hours, forming this same salt. The crystals dissolve slowly in cold but rapidly in warm water. H. St. C. Deville made some observations on this subject. F. Jeremin noted that when conc. sulphuric acid is gradually added to a conc. aq. soln. of aluminium sulphate, there is a precipitation of hydrated aluminium sulphate, and with 5 c.c. of soln. to 0·3 c.c. of acid, the precipitate has the composition $Al_2(SO_4)_3.22H_2O$; but with equal volumes of acid and soln., the precipitate is decahydrated **aluminium tetrahydrosulphate,** $Al_2(SO_4)_3.2H_2SO_4.10H_2O$, or $Al_2(SO_4)(HSO_4)_4.10H_2O$, and with 20 c.c. of acid to 5 c.c. of soln., there is scarcely any turbidity produced. The maximum precipitation occurs with 5 c.c. of soln. and 1·5 c.c. of acid. J. Kendall and A. W. Davidson found the molar solubility of anhydrous aluminium sulphate in anhydrous sulphuric acid at 25° to be below 0·01. According to R. Silberberger, heptahydrated aluminium hexahydrosulphate, $Al_2(SO_4)_3.3H_2SO_4.7H_2O$, *sulphatoaluminic acid,* $Al_2(HSO_4)_6.7H_2O$, or, as he calls it, *aluminosulphuric acid,* is prepared by adding aluminium sulphate to cold conc. sulphuric acid and warming, when a voluminous white precipitate separates. On diluting with ether, filtering, and washing with ether, the acid is obtained as a white powder, decomposing in moist air and dissolving in water, the soln. soon decomposing into aluminium sulphate and sulphuric acid. The addition of barium chloride to conc. sulphuric acid soln. of aluminium sulphate furnishes a complex *barium sulphatoaluminate* which immediately decomposes.

Basic aluminium sulphates.—The alleged formation of basic aluminium sulphates by the hydrolysis of aq. soln. of aluminium sulphate has been previously described. L. Liechti and W. Suida [5] observed no visible hydrolysis on heating or diluting a soln. of 200 grms. $Al_2(SO_4)_3.18H_2O$ in a litre of water; with a soln. of 200 grms. $Al_2(SO_4)_3.18H_2O$ and 31·82 grms. of sodium carbonate per litre, there was no visible change on heating, but a precipitate formed when the soln. was diluted four-fold; with a soln. three-fourths as conc. there was no visible change on heating, but dissociation occurred on diluting ten-fold. With a soln. made from 200 grms. of $Al_2(SO_4)_3.18H_2O$ and 45·7 grms. of sodium hydrocarbonate per litre, a jelly was formed on heating, and a precipitate remained on cooling; while diluting the soln. one-half caused a precipitate to appear in the cold. A soln. of 300 grms. of $Al_2(SO_4)_3.18H_2O$ and 151·3 grms. of sodium hydrocarbonate per litre, became turbid in a very short time. Hence, hydrolysis occurs more readily (i) the more basic the soln., (ii) the more dilute the soln., and (iii) the higher the temp. L. Liechti and W. Suida added that sodium sulphate accelerated the hydrolysis, but L. Liechti and H. Schwitzer said it retarded the decomposition. The latter statement accords with H. Schmid's observation that sodium sulphate retards the precipitation of alumina by sodium carbonate.

According to H. G. Denham, the percentage **hydrolysis,** $100x$, of aq. soln. of aluminium sulphate, calculated on the assumption that the reaction is represented by $Al_2(SO_4)_3+2H_2O \rightleftharpoons 2Al(SO_4)HO+H_2SO_4$, for soln. with a mol of the salt in v litres of water at 25°, is:

v	4	8	16	32	64	256
$100x$	0·522	0·748	1·160	2·016	3·492	9·600

Values have also been obtained by H. Ley, L. Kahlenberg and co-workers, L. Bruner, and G. Carrara and G. B. Vespignani. According to J. L. Gay Lussac, aluminium hydroxide dissolves in aq. soln. of aluminium sulphate. The freshly prepared hydroxide dissolves fastest, and attains equilibrium more quickly than the aged hydroxide. R. Kremann and K. Hüttinger measured the solubility of aluminium hydroxide in soln. of aluminium sulphate of different conc. at 20°, 40°, and 60°. Expressing conc. in grams of sulphate and hydroxide per 100 grms. of water, and molar proportions $Al_2O_3 : SO_3 : H_2O$ as a ratio, the results at 20° are:

$Al_2(SO_4)$	2·37	5 0	9·1	15 0	20 0	31·6	33·0	34·73
$Al(OH)_3$	0·15	0·30	1·30	1·04	1·40	4·20	2 75	0·92
Solid phase		1 : 1 . 9	$\rightleftharpoons$	1 : 2 12		$\rightleftharpoons$	1 . 3 16	

The results for two temp. are indicated in Fig. 65, where the solid phase is $Al_2O_3.SO_3.9H_2O$ along *ab* and *ab'*; $Al_2O_3.2SO_3.12H_2O$ along *bc* and *b'c'*; and $Al_2(SO_4)_3.16H_2O$, along *cd* and *c'd'*. They represent the constitution of these two hydrated basic salts as derivatives of $Al_2O(OH)_4$, thus:

$$O<\begin{matrix}Al=(OH)_2\\Al=(OH)_2\end{matrix}$$

$$O<\begin{matrix}Al<\begin{matrix}OH\\SO_4\end{matrix}\\Al<OH\end{matrix}$$

$$O<\begin{matrix}Al\\Al\end{matrix}>(SO_4)_2$$

Numerous other basic hydrates have been reported. Many are no doubt intermediate stages in the hydrolysis of the normal sulphate, and available evidence is not sufficient to establish their chemical individuality. S. U. Pickering regarded them as mixtures whose composition depends on the conditions under which they were prepared. Thus, O. Schmatolla, under various conditions of precipitation, obtained hydrated basic products with $Al_2O_3 : SO_3$ as 6 : 1, 12 : 1, 24 : 1, and 48 : 1. L. B. Miller, F. S. Williamson, and E. J. Thericault and W. M. Clark studied the products of the partial alkalization of soln. of alum.

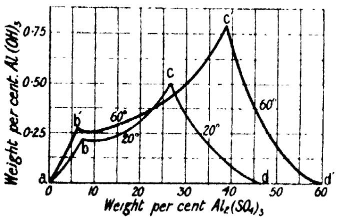

FIG. 65.—Solubility of Aluminium Hydroxide in Solutions of Aluminium Sulphate at 25°.

E. Schlumberger reported that the precipitate formed when aluminium sulphate is exactly neutralized with alkali-lye consists of dihydrated **tetraluminium decahydroxysulphate** having the composition $2Al_2O_3, SO_3, 7H_2O$. He called it *hydrate sulfodialuminique.*

The same sulphate is precipitated when sodium aluminate is neutralized with alum, or when a soln. of alum, to which alkali has been added until a slight permanent precipitate is formed, is boiled, or when a soln. of aluminium acetate is boiled with alkali sulphates. It is stable only in the presence of alkali sulphates, and is partially dissolved by water. The dry substance loses $2H_2O$ at 130°, and forms the pentahydrate but is otherwise stable. It is soluble in cold acetic acid, but is reprecipitated on boiling, and redissolves on cooling, in this resembling the ordinary aluminium mordanting soln., the essential constituent of which appears to be an acetate and sulphate. He considers the hydrate to be constituted $Al_2(OH)_5]_2SO_4$. According to F. S. Williamson, E. Schlumberger's product is a mixture. When 2 to 4 mols of sodium hydroxide are added to a soln. of one mol of aluminium sulphate, the precipitate has the composition $Al_2(SO_4)_3.(Al_2O_3)_4.15H_2O$, *i.e.* **deca-aluminium hydroxytrisulphate,** $Al_2(SO_4)_3.8Al(OH)_3.3H_2O$. The substance loses less than one-tenth of its water over conc. sulphuric acid at ordinary temp., and all is lost at 150°. Less than one-third is taken up again at lower temp. so that the reaction is not reversible.

D. Köchlin-Schouch, and W. Crum made the decahydrate, $2Al_2O_3.SO_3.10H_2O$, by boiling aluminium acetate with a soln. of potassium sulphate; L. F. Bley made the dodecahydrate by adding an excess of alkali carbonate to a soln. of alum. The decahydrate is represented in nature by the rhombic mineral *felsöbanyite* which, according to W. Haidinger has the sp. gr. 2·33, and hardness 1·5. It was found in snow-white or yellowish masses at Kapnik (Hungary). The pentadecahydrate, $2Al_2O_3.SO_3.15H_2O$, is represented by the mineral *paraluminate*, closely related to aluminate, which occurs near Halle, Huelgoet (Brittany), etc. Analyses were made by P. Berthier, C. Steinberg, H. Backs, E. Wolff, R. Dieck, L. J. Lassaigne, and R. Geist. The related *pissophane*—from πισσα, pitch; φανός, appearance—of A. Breithaupt, analyzed by O. L. Erdmann, contains much ferric oxide.

H. Debray reported $5Al_2O_3.3SO_3.20H_2O$ to be formed by boiling an excess of an aq. soln. of aluminium sulphate with zinc; L. F. Bley, $3Al_2O_3.2SO_3.2H_2O$, by the incomplete precipitation of a soln. of aluminium sulphate with aq. ammonia; C. J. Bayer, $3Al_2O_3.2SO_3.9H_2O$, by boiling a soln. of aluminium sulphate with an excess of aluminium hydroxide; A. Lowe, and H. Debray, $4Al_2O_3.3SO_2.36H_2O$, and $8Al_2O_3.5SO_3.25H_2O$, by the action of zinc on a cold soln. of aluminium sulphate in excess; N. Athanasesco, $3Al_2O_3.4SO_3.9H_2O$, in colourless rhombohedra, by heating a 3 per cent. soln. of normal aluminium sulphate to 250° in a sealed tube; and C. F. Rammelsberg, $3Al_2O_3.4SO_3.30H_2O$, as a crust on the sides of a glass bottle in which dil. sulphuric acid sat. with aluminium hydroxide, was kept many years. R. Phillips found a moderately dil. sulphuric acid soln. of aluminium hydroxide, on being mixed with water, deposits for many months a basic salt of composition similar to C. F. Rammelsberg's salt; and J. L. Gay Lussac added that the filtrate has a similar composition, and becomes turbid as often as it is warmed. S. U. Pickering found that the addition of sodium hydroxide to a soln. of aluminium sulphate completes the precipitation when the quantity added reaches 1·833 eq. implying the possible formation of $5Al_2O_3.6SO_3.nH_2O$. J. Gadamer reported $Al_2(SO_4)_3.Al_2(OH)_6.9H_2O$, or $2Al_2O_3.3SO_3.12H_2O$, to be formed by slowly evaporating a mixed soln. of potassium chromate and aluminium sulphate—the first crop of crystals is potash-alum, then potassium dichromate, and then the 2 : 3 : 12 salt, while chromic acid remains in soln. F. Gobel, and N. Mill also reported $2Al_2O_3.3SO_3.nH_2O$.

O. Schmatolla obtained a basic sulphate $Al_2O_3.SO_3.nH_2O$ by the action of calcium carbonate on a cold soln. of aluminium sulphate. According to J. J. Berzelius, heptahydrated **aluminium tetrahydroxysulphate,** $Al_2(SO_4)(OH)_4.7H_2O$, or $Al_2O_2(SO_4).9H_2O$, is produced by washing the precipitate obtained by adding aq. ammonia to a soln. of aluminium sulphate. L. F. Bley—*vide supra*—said that the product is more basic than J. J. Berzelius supposed. C. Böttinger found that the tetrahydrate, $Al_2(OH)_4SO_4.4H_2O$, or $Al_2O_3.SO_3.6H_2O$, is deposited when an aq. soln. with 5 grms. of aluminium sulphate and 1·5 grms. of sodium chloride is heated in a sealed tube at 140°. The heptahydrate is represented by the earthy mineral *aluminite* of D. L. G. Karsten, the *hallite* of J. C. Delamétherie, the *reine Tonerde* of A. G. Werner, the *native argill* of R. Kirwan, the *websterite* of J. Brooke, and F. S. Beudant. It was analyzed by F. Stromeyer, A. Dufrénoy, C. Steinberg, etc. Its sp. gr. is 1·705 and hardness between 1 and 2.

According to P. Marguerite, when ammonia alum is decomposed by heat, anhydrous aluminium sulphate is first obtained, but pushing the decomposition somewhat further, sulphuric acid is volatilized; so that by carefully regulating the heat, a residue can be finally obtained almost entirely soluble in water, and consisting mainly of hexahydrated **aluminium dihydroxydisulphate,** $Al_2O_3.2SO_3.12H_2O$, or $Al_2(SO_4)_2(OH)_2.11H_2O$. This salt, which has not been before described, is entirely different in appearance from the ordinary sulphate. It ystallizes in rhombohedrons and not in nacreous scales; its solubility in water at 5° is about 45 per cent., but it can be separated from the ordinary sulphate by ractional crystallization. A. Maus obtained this hydrosulphate by evaporating to dryness a hot filtered soln. of normal or basic aluminium sulphate and hydroxide. The product is a sticky mass. H. Spence made it by mixing a soln. of aluminium sulphate with enough calcium hydroxide or carbonate to give the necessary basicity. The filtered soln. was evaporated in vacuo. The mineral *alumian* was obtained by A. Breithaupt from Sierra Almagrera (Spain); it has the same composition as P. Marguerite's salt. Its sp. gr. is 2·702-2·781, and its hardness 2 to 3. In the progressive dehydration of alumian, R. Kremann and K. Hüttinger found breaks in the vap. press. curve corresponding with the hydrates 1 : 2 : 12; 1 : 2 : 11; and 1 : 2 : 10.

What has been regarded as a *basic subsulphate* was obtained by F. Fischer as a blue anode deposit when sulphuric acid of sp. gr. 1·175 is electrolyzed with aluminium electrodes. Layers of a bluish-green tint are deposited on the anode, especially when the electrolyte is kept cool; the portions of the deposit next to the electrode are, however, intensely blue. Microscopic examination indicated that this blue deposit is not a uniform substance. It is not acted on by distilled water. Dil. hydrochloric acid of such a strength as to act vigorously on aluminium at the ordinary temp. has scarcely any action on it. When warmed with hydrochloric acid, hydrogen is evolved, traces of silicic acid remaining; the filtrate gives a precipitate with barium chloride and also contains aluminium. The product is free from sulphide and contains a basic aluminium sulphate, a little silicic acid, and traces of iron. When heated, it becomes white.

§ 20. The Complex Salts of Aluminium Sulphate

The aluminium salts have a marked tendency to form complexes; and this is well illustrated by the sulphate which forms a series of complex salts of the type $R_2'SO_4.Al_2(SO_4)_3.24H_2O$, or $R'Al(SO_4)_2.12H_2O$, where R' represents a univalent radicle; these salts are grouped under the generic term **alums.** The univalent elements which take part in the formation of alums are: thallium, cæsium, rubidium, potassium, and sodium and possibly lithium and silver—as well as the univalent radicles ammonium, hydroxylamine, and alkyl-ammonium. Ten tervalent elements can act instead of aluminium; thus, titanium, vanadium, chromium, manganese, iron, cobalt, gallium, indium, iridium, and rhodium. Excluding lithium, silver, hydroxylamine, and alkylammonium, this makes 66 members of the alum-family. In addition, a number of selenic alums have been obtained in which selenium replaces the sulphur; and E. von Gerichten[1] obtained other alums in which one component is a selenate and the other a sulphate. This would make 264 alums. Only a fraction of these combinations has been obtained. No attempt has been made to prepare some of them, and with others, the attempt has failed owing to the instability of the complex. Allowing for the relatively low stability of the tervalent forms of some of the elements, as a rule, the greater the mol. wt. of the univalent radicle, the greater the stability of the alum, and conversely, the greater the mol. wt. of the tervalent metal the less the stability of the alum. Thus, sodium forms alums only with the lighter tervalent elements—aluminium, vanadium, and chromium; the only stable potash alums are those of aluminium and chromium; and with some tervalent elements the rubidium and cæsium alums are the only stable forms. If an element will form an alum, J. Locke has stated that it will do so more readily with cæsium sulphate than with any of the other alkali sulphates. He said, "If an alum cannot be formed with cæsium sulphate, it cannot be formed at all." The sulphate-alums which have been reported are indicated in Table VI.

TABLE VI. ALUM-FORMING ELEMENTS (SULPHATES).

	Al	Cr	Fe	Co	Ga	In	V	Ti	Mn	Rh	Ir
Na	1	1	0	0	0	0	0	0	0	0	0
K	1	1	1	0	1	0	1	0	0	1	1
NH_4	1	1	1	0	1	1	1	0	0	1	1
Rb	1	1	1	1	1	1	1	1	1	1	1
Cs	1	1	1	1	1	1	1	1	1	1	1
Tl	1	1	1	1	1	0	1	0	0	1	1

F. B. Venable tried to make double alkali alums by crystallization from mixed soln. of potash-alum and soda-alum, but he obtained only a variable mixture of crystals of the two salts, in which the inferior solubility of potash-alum makes this salt predominate in the isomorphous crystals. H. Schiff, and R. Krickmeyer obtained similar results with mixtures of potash-alum and ammonia-alum. S. Kern claimed to have made *silver alum*, or **silver aluminium sulphate,** $Ag_2SO_4.Al_2(SO_4)_3.24H_2O$, by evaporating a soln. of molar proportions of the constituent salts; and A. H. Church and A. B. Northcote by heating silver sulphate, aluminium sulphate, and water contained in a sealed tube on an oil-bath. The latter say that the octahedral crystals are decomposed by water.

Some of the alums occur in nature. The so-called *mendozite* found at San Juan Mendoza, east of the Andes, was analyzed by T. Thomson,[2] but the water of crystallization is not that of the alums. J. J. N. Huot called it *natroalun*. C. U. Shepard proposed calling soda-alum *solfatarite*; and he reported that the native alum on the island of Milo is a soda-alum, but later he accepted C. Hartwell's analyses, which makes it an alunogen. According to E. Divers, the native soda-alum from Shimane, Idzumo, Japan, has the typical alum formula. The mineral *tamarugite* obtained by H. Schulze from the Pampa del Tamarugal, Cerros Pintados, Chili, has the composition of soda-alum, but only half the water of crystallization of an alum proper. L. Domeyko's *alumbre nativo* has a similar composition. The mineral *stüvenite* from Copiapo is a soda-alum with up to half the sodium replaced by magnesium (*vide infra*). In 1792 S. Breislak, and in 1795 M. H. Klaproth, showed that the alum from Miseno and Solfatara, near Naples, is potash-alum. The latter said: "The *grotto di alume* at Miseno, Naples, serves as a laboratory where nature alone, unassisted by art, is constantly producing perfect alum." J. D. Dana called native alum *kalinite*. It occurs as an efflorescence on argillaceous minerals—*e.g.* the alum shales of Whitby; at Hurlet and Campsie near Glasgow; at the volcanoes of Lipari and Sicily; Cape Sable, Maryland; Sevier, Tennessee; Brandfeldern, Saarbrücken, etc. F. S. Beudant, and W. Grüner showed that ammonia alum occurs as a mineral which was called by F. von Kobell *tschermigite*, after Tschermig, Bohemia, where the salt occurs. It has also been obtained from Wamsutter (Wyoming), Dux (Bohemia), Tokod (Hungary), and the crater at Etna. Analyses were made by C. H. Pfaff, W. A. Lampadius, F. Stromeyer, L. R. Lecanu and M. Blanchet, etc. T. Garnett, speaking of one of the sulphur wells of Harrogate, said: "I have discovered alum therein, and I suspect salited clay." A. Hunter found none. R. H. Davis analyzed one of the old alum wells of Harrogate and found 89·47 grains of aluminium sulphate, 3·14 potassium sulphate, and 2·19 ammonium sulphate per gallon.

L. Kralovansky[3] stated that the evaporation, at temp. below 11°, of a mixed soln. of lithium and aluminium sulphates furnishes octahedral and dodecahedral crystals of *lithia-alum*, or **lithium aluminium sulphate,** $Li_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *lithium disulphato-aluminate*, $LiAl(SO_4)_2.12H_2O$. *Au contraire*, C. F. Rammelsberg was not able to prepare the double sulphate and said that it does not exist. F. A. H. Schreinemakers and A. J. C. de Waal, in their study of the ternary system, $Li_2SO_4-Al_2(SO_4)_3-H_2O$, found for the percentage composition of the soln. at 30°:

Li_2SO_4 . .	25·1	21·93	16·10	13·63	11·73	6·75	3·44	0
$Al_2(SO_4)_3$.	0	5·34	14·89	20·76	22·08	24·34	26·12	28·0
Solid phases . .	$Li_2SO_4.H_2O$			$Al_2(SO_4)_3.18H_2O$				

The line *ab*, Fig. 66, represents the solubility of hydrated lithium sulphate; *bd*, the solubility of the same salt in a metastable condition; *b*, a transition point; *bc*, the solubility of octodecahydrated aluminium sulphate. Consequently, the only solid phases at 30° are $Li_2SO_4.H_2O$ and $Al_2(SO_4)_3.18H_2O$; but this does not say what would occur at the lower temp. expressly mentioned by L. Kralovansky.

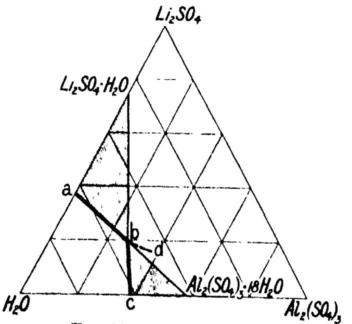

FIG. 66.—Ternary System, $Li_2SO_4-Al_2(SO_4)_3-H_2O$, at 30°.

K. G. Wellner[4] stated that *soda-alum* crystallizes from the mother liquid remaining after the separation of potash-alum when soap-boiler's lye, containing sodium chloride, has been employed in the preparation. P. Zellner obtained octahedral crystals of soda-alum by the spontaneous evaporation of a mixed soln. of sodium and aluminium sulphates. Analyses of the salt by K. G. Wellner, P. Zellner, A. Ure, T. Graham and W. R. Smith agreed with **sodium aluminium sulphate,** $Na_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *sodium disulphatoaluminate*, $NaAl(SO_4)_2.12H_2O$. According to J. B. Spence, the crystals are obtained from soln. of sp. gr. 1·30, if more conc., say by cooling a hot conc. soln., a viscid mass is obtained, which crystallizes very slowly. These statements have been confirmed by J. M. Wadmore, E. Augé, G. Dumont, etc. G. Bergeron, and W. Beatson have described the manufacture of soda-alum. E. Augé said that the soln. of the mixed salts cannot be evaporated in the ordinary way to the density necessary for crystallization without employing a temp. of at least 73°–80°, and the soda-alum soln. when heated to this degree is rendered incapable of crystallizing. E. Augé obviates this difficulty by conducting the evaporation under reduced press., and obtains the required sp. gr. (1·38 to 1·46) at a temp. of about 48°—in no case exceeding 60°. J. Bock added that if the soln. is made slightly alkaline by the addition of basic aluminium sulphate, the formation of the viscid mass does not occur. W. R. Smith said that the best way of making soda-alum is to dissolve the component salts in an amount of water sufficient to give a soln. moderately supersaturated at ordinary temp., and then cool the soln. inducing crystallization by stirring or seeding. This gives small crystals similar to alum-meal; if larger crystals are desired, the soln. should be slowly evaporated at ordinary temp. As in the case of lithia-alum, the existence of soda-alum has been denied—*e.g.* W. Ostwald has said that the place of potassium in potash-alum cannot be taken by sodium or lithium. The individuality of soda-alum is now well established, but that of lithia-alum is still *sub judice*.

The general method of preparing alums is to crystallize the complex salt from a mixed soln. of the component salts. L. Geschwind,[5] K. W. Jurisch, F. Jünemann, D. G. Fahrenheit, J. M. Wilson, and L. Pommier have written monographs on the manufacture of alum. The analyses of T. Thomson, L. J. Thénard and M. Roard, L. N. Vauquelin, T. Graham, and J. Lowe show that *potash-alum* corresponds with **potassium aluminium sulphate,** $K_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *potassium disulphato-aluminate*, $KAl(SO_4)_2.12H_2O$. As indicated in connection with the history of aluminium, the manufacture of alum from alum-rock or alunite—a basic potassium aluminium sulphate, *vide infra*—dates from early times. The aq. extract from the roasted ore contains sufficient potassium and aluminium to furnish a crop of crystals of potash-alum. L. Duncan has described the process with the ore at Tonopah. A. Matheson, J. L. Silsbee, etc., have suggested modifications of the process. T. H. Wright treated a soln. of potassium chloride with magnesium sulphate, and added a soln. of aluminium sulphate to make the sp. gr. about 1·384. The soln. was heated to 90°, and cooled for crystals of potash-alum. As shown by A. F. Gehlen, the so-called *Roman alum*, as formerly prepared, had a higher degree of purity than ordinary alum; the crystals were usually cubic. Alum is to-day manufactured of an equally high degree of purity. H. T. S. Britton studied the ternary system, $Al_2(SO_4)_3-K_2SO_4-H_2O$, at 25°, and his results are summarized in Fig. 67, where the ordinates represent the number of grams of water in which 100 grms. of the solute dissolve to give a sat. soln. Indications of the solid phases K_2SO_4, alum, $Al_2(SO_4)_3.18H_2O$, were obtained. Potash alum is also made from alum shales which contain pyrites, and sometimes, according to H. Müller, organic sulphides. Various processes of manufacture have been indicated in connection with the extraction of alumina (*q.v.*).

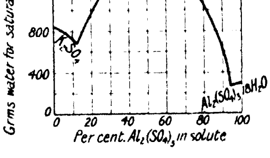

Fig. 67.—The Ternary System, $K_2SO_4-Al_2(SO_4)_3-H_2O$, at 25°.

W. A. Lampadius discussed the formation of alum from mixtures of pyrites and clay. The sulphides in the alum-shales and alum-clays can be oxidized by weathering or by a low-temp. roasting. The oxidized ore is leached with dil. sulphuric acid, and the soln. mixed with potassium sulphate; the hot conc. soln. is rapidly cooled while being agitated, when small crystals of *alum-meal* are deposited. This product is drained and washed with the mother liquor from the block-alum crystallization. The alum-meal is purified by dissolving it to form a hot sat. soln., which is clarified by the addition of a little size to precipitate the suspended matters. The clear soln. is decanted into vats fitted with movable staves. Large crystals of *block-alum* collect on the staves. In a few days, the staves are removed, and holes bored in each mass of block-alum to allow the mother liquor to drain away. The block-alum is then broken up for the market. When the shales contain much iron, the ferric sulphate can be converted into chloride by the addition of potassium chloride alone or mixed with the sulphate. The iron then remains in soln. as ferric chloride instead of crystallizing as an isomorphous iron alum. J. Bock studied the conditions favourable for the formation of large crystals.

Alum is also manufactured from blast furnace slags, bauxites and other hydrated forms of alumina, clays and other alumino-silicates. J. W. Hinchley described the manufacture of alum from leucite. These silicates may or may not be advantageously calcined at a low temp. to make them more susceptible to attack by sulphuric acid. C. Schwartz considered the best calcining temperature to be about 500°, and the best concentration of the acid to be that with a sp. gr. between 1·297 and 1·530. According to L. Geschwind, the calcination temperature employed in France is 1000°—*vide* "clays" for the effect of the temperature of calcination on the solubility. On a manufacturing scale other factors are involved —*e.g.* the tendency of the mass being extracted to retain its porous granular form, or to disintegrate into a compact powder not easily penetrated by the acid. In preparing crude soln. of aluminium sulphate, powdered bauxite is boiled with dil. sulphuric acid until nearly neutral. The dil. liquor containing finely-divided residue in suspension is allowed to settle, and the liquor cleared by filter-press or other means. To eliminate the difficulties attending the removal of finely divided, undissolved residue from the liquor, W. B. Llewellyn and H. and P. Spence use a bauxite or clay which retains its form, without disintegration, during the extraction with acid.

The granular material ignited or not ignited is placed in a series of vats with false bottoms; a hot soln. of aluminium sulphate with free acid from a previous extraction is first allowed to percolate through the mass, and afterwards other hot or boiling soln., containing progressively more and more free acid, are passed through the materials. Weak liquors from previous operations and finally water are allowed to circulate through the exhausted bauxite, which is then allowed to drain. The exhausted bauxite is replaced by fresh material, which then takes its place in the cycle of operations. The clear neutral or basic soln. of aluminium sulphate can then be purified from iron, and converted into alum, etc. The process has also been adapted to aluminous clays, etc.

P. Spence (1870) described a process of making alum from mineral phosphates; T. J. Herapath prepared alum from the ashes of boghead coal; and G. Clemm utilized the sulphates from the Stassfurt deposits by adding to each mol of aluminium chloride in hydrochloric acid soln., one mol of schönite and 2 mols of kieserite: $2AlCl_3 + K_2SO_4 + 3MgSO_4 = 3MgCl_2 + K_2SO_4.Al_2(SO_4)_3$. The alum readily crystallizes out leaving the magnesium chloride in soln. Some have prepared alum by using potassium chloride, *e.g.* T. H. Wright treated a soln. of that salt with sodium sulphate, and then added aluminium sulphate to the slightly acid soln. Potash-alum crystallizes out. The use of potassium chloride in place of the sulphate hinders the formation of iron-alum isomorphous with ordinary alum, and is used where sufficient iron sulphate is present to supply the necessary sulphuric acid to produce alum. The alkali chloride converts the ferric and ferrous sulphates to the more soluble chlorides. An excess of alkali chloride would attack the aluminium sulphate, and produce aluminium chloride which would be lost. A. R. Lindblad and S. H. Hultman have discussed the removal of iron from aluminium sulphates.

The manufacture of *ammonia-alum* is conducted in a manner analogous to that of potash-alum when ammonium sulphate, produced from waste liquors from gas-works, is used in place of potassium sulphate. The analyses of F. Stromeyer, A. Riffault, and G. Forchhammer have shown this salt corresponds with **ammonium aluminium sulphate,** $(NH_4)_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *ammonium disulphatoaluminate,* $NH_4Al(SO_4)_2.12H_2O$. W. Meyeringh prepared typical crystals of *hydroxylamine-alum,* or **hydroxylamine**

aluminium sulphate, $(NH_3OH)_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *hydroxylamine disulphatoaluminate*, $(NH_3OH)Al(SO_4)_2.12H_2O$, in an analogous manner. Typical crystals of *rubidia-alum*, or **rubidium aluminium sulphate,** $Rb_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *rubidium disulphato-aluminate*, $RbAl(SO_4)_2.12H_2O$; and of *cæsia-alum*, or **cæsium aluminium sulphate,** $Cs_2SO_4.Al_2(SO_4)_3.24H_2O$, or dodecahydrated *cæsium disulphatoaluminate*, $CsAl(SO_4)_2.12H_2O$, were prepared by G. Kirchhoff and R. Bunsen from a soln. of the component salts. S. Kern claims to have made typical crystals of *silver-alum*, or **silver aluminium sulphate,** $Ag_2SO_4.Al_2(SO_4)_3.24H_2O$, or *silver disulphatoaluminate*, $AgAl(SO_4)_2.12H_2O$, by evaporating mixed soln. of the component salts; and A. H. Church and A. B. Northcote, by heating in an oil-bath a mixture of silver sulphate with aluminium sulphate and water until the silver salt had all dissolved; on cooling, typical crystals of silver-alum were formed. J. W. Retgers has denied the existence of silver-alum.

The cubic **crystals** of alum appear as octahedra when crystallized from aq. soln. In 1772, A. M. Sieffert,[6] and in 1802, N. le Blanc, showed that if the soln. be made alkaline by the addition of lime, or alkali carbonate, the crystals are in cubes—*cubic alum*. F. S. Beudant likewise obtained cubic crystals by the addition of a little borax; C. von Hauer, ammonia, and H. Kopp, alkali-lye. E. Jannettaz examined the effect of aluminium and ammonium chlorides, and hydriodic and sulphuric acids; and T. J. Pelouze and E. Frémy, P. A. Schemjatschensky, N. S. Kurnakoff, A. Schubnikoff, F. S. Beudant, A. Stiassny, F. Klepatschewsky, H. Kopp, J. F. Persoz, A. Polis, A. Knop, and R. Weber, the effect of hydrochloric acid. Other observations have been made by A. Scacchi, H. A. Miers, F. Klocke, L. Wulff, P. Gaubert, A. Rauber, Z. Weyberg, H. Przibram, A. Korbs, and A. Rota. L. Vegard and co-workers studied the **X-radiograms** of potash- and ammonia-alums, and could find no distinction between the water of crystallization and the other constituents of alum. The subject has been also discussed by J. J. P. Valeton, C. Schäfer and M. Schubert, T. Terada, and P. Niggli. L. Vegard and H. Schjelderup showed that the sides of the unit cubes containing four chemical molecules of potash-alum are $12{\cdot}08\times10^{-8}$ cms., and of ammonia-alum, $12{\cdot}00\times10^{-8}$ cms. R. W. G. Wyckoff said that the hemihedral structure of the alums has in a unit cell four mols. with the composition $R'R'''(SO_4)_2.12H_2O$, and in this space group the four sulphate oxygen atoms cannot be exactly alike. Three are similarly placed, but four are different from the other three; the 12 mols. of water fall into two groups—six in each. The **corrosion figures** have been examined by F. Klocke, and L. Wulff; the **rates of dissolution** of the difference faces of the crystal, by J. J. P. Valeton; and the **percussion figures**, by M. Kuhara.

The formation of **supersaturated solutions** by cooling hot sat. soln. in closed vessels was described by H. Löwel; and L. de Boisbaudran, by mixing conc. soln. of the component salts in a vessel protected from atm. dust. The last-named found that if a soln. be evaporated at 75°–80° while protected from dust, the supersaturated soln. furnishes a hard glassy mass which does not crystallize in contact with crystals of alum, but if moisture be present, the glass becomes opaque and crystalline. A. Jeannel found that when the glassy mass does crystallize much heat is evolved, and the mass expands considerably; he also found that a thin layer of a soln. of alum does not crystallize on glass. According to J. M. Thomson and W. P. Bloxam, a supersaturated soln. of alum may be inoculated with either potassium sulphate or octodecahydrated aluminium sulphate without crystallization. H. Schiff, and R. Krickmeyer found that ammonia- and potash-alum form a continuous series of **mixed crystals**; F. P. Venable studied the mixed crystals of soda- and potash-alums. C. Soret reported that soda-alum can be obtained in monoclinic prisms with axial ratios $a:b:c=2{\cdot}5060:1:0{\cdot}9125$, and $\beta=109^\circ\ 1'$, by pouring a layer of alcohol over a sat. aq. soln. of soda-alum at 8° 12°. P. Groth assumes that soda-alum is dimorphous—monoclinic and cubic. C. Soret's analysis corresponded with $Na_2SO_4.Al_2(SO_4)_3.23H_2O$; but N. I. Surgunoff's investigation shows that the salt is docosihydrated $Na_2SO_4.Al_2(SO_4)_3.22H_2O$, or *henadecahydrated sodium disulphatoaluminate*, $NaAl(SO_4)_2.11H_2O$—corresponding with T. Thomson's analysis of mendozite—and if the supersaturated soln. crystallizes at 20° or less, cubic crystals are formed, and if at a higher temp., monoclinic crystals are produced.

The **specific gravity** of *lithia-alum* is not recorded; that of *soda-alum* has been determined by R. Krickmeyer—1·675; H. Schiff[7]—1·641; O. Pettersson—1·691 (18°); C. Soret—1·73; A. Ure—1·60; H. J. Buignet—1·567; that of *potash-alum* by H. Schiff—1·722; O. Pettersson—1·752; R. Krickmeyer, and M. le Blanc and P. Rohland—1·757; A. Dufrenoy—1·753; H. J. Buignet—1·757; F. Stolba—1·7505; W. C. Smith—1·753; J. H. Hassenfratz—1·17109; H. Kopp—1·724; L. Playfair and J. P. Joule—1·726, or 1·75125 at 4°; H. G. F. Schröder—1·711; and C. Soret—1·666–1·669; that of *rubidia-alum* by J. Redtenbacher—1·874; C. Setterberg—1·884 at 20·6°; C. Soret—1·852; that of *cæsia-alum* by J. Redtenbacher—2·003; E. Hart and H. B. Huselton—1·945; and C. Soret—1·911; and that of *ammonia-alum* by L. Playfair and J. P. Joule—1·625; R. Krickmeyer—1·645; H. Schiff—1·621; H. J. Buignet—1·653; O. Pettersson—1·642 at 18·8°; W. C. Smith—1·661; H. Kopp—1·626; A. Breithaupt—1·602; and C. Soret—1·631. The best representative values between 18° and 20° are:

	Na	K	Rb	Cs	NH_4-alum
Sp. gr. . . .	1·68	1·75	1·88	1·95	1·64

T. Thomson gave 1·88 for mendozite. C. Soret gave for his monoclinic soda-alum, 1·728–1·733. For dehydrated potash-alum, L. Playfair and J. P. Joule gave 2·228; and O. Pettersson, 2·6875 at 15°; for dehydrated rubidia-alum, the last-named gave 2·7821 at 14·9°; and for dehydrated ammonia-alum, L. Playfair and J. P. Joule gave 2·039. W. Spring measured the effect of *temperature* on the sp. gr., and found this to be:

	0°	10°	20°	30°	50°	70°	90°	100°
Potash-alum . .	1·7546	1·7542	1·7538	1·7532	1·7521	1·7474	1·7067	—
Rubidia-alum . .	1·8667	1·8648	1·8639	1·8635	1·8624	1·8611	1·8578	1·8554
Cæsia-alum .	2·0215	2·0210	2·0205	2·0200	2·0189	2·0173	2·0107	2·0061
Ammonia-alum. .	1·6357	1·6351	1·6346	1·6345	1·6336	1·6328	1·6209	1·6275

J. Dewar gave 1·6414 for the sp. gr. of potash-alum at the temp. of liquid air, about −180°; when the sp. gr. at 17° is 1·6144. W. Spring also measured the effect of *pressure* (20,000 atm.) on the sp. gr.:

	Not pressed.	Once pressed.	Twice pressed.
Potash-alum	1·758 (21°)	1·756 (16·5°)	1·750 (16·5°)
Cæsia-alum	1·988 (18°)	2·000 (20°)	2·005 (20°)
Ammonia-alum . . .	1·641 (18°)	1·629 (16·5°)	1·634 (18°)

A. Ure found that an *aqueous solution* of soda-alum sat. at 15·5° had a sp. gr. 1·296, and contained 110 parts of salt per 100 parts of water. E. F. Anthon gave 1·045 for the sp. gr. of a soln. of potash-alum sat. at 8°; and G. T. Gerlach gave

Potash-alum	4	8	12	13 per cent.
Sp. gr. 17·1°/17·1°	1·0205	1·0415	1·0635	1·0690

Measurements with soln. of potash-alum were made by A. Michel and L. Kraft, E. Forster, M. le Blanc and P. Rohland, and F. Stolba. F. Fouqué found the sp. gr. of a 11 per cent. soln. of potash-alum to be 1·0093 and 1·0090 respectively at 0° and 12°; and of a 34·2 per cent. soln., 1·0304 and 1·0298 respectively at 0° and 9°. He likewise found the sp. gr. of a 3·2 per cent. soln. of rubidia-alum to be 1·0025 and 1·0021 respectively at 0° and 12°. J. G. MacGregor found that the sp. gr., D, of a soln. of potash-alum at 20° containing w per cent. of the anhydrous salt, up to $w=2·5$, is $D=D_0+0·0095187w$, where D_0 represents the sp. gr. of water at 20°. According to R. Broom, the dissolution of 4·99 grms. of dehydrated potash-alum in 100 c.c. of water is attended by a contraction of 0·033 per cent. G. T. Gerlach measured the sp. gr. of soln. of ammonia-alum; and M. Hoek and J. A. C. Oudemans, of soda-alum. J. Beckenkamp measured the **torsion modulus** or rigidity of crystals of potash-alum, and found 1806 kgrms. per sq. mm. for a cube face, and 1987 kgrms. per sq. mm. for an octahedron face. D. M. Torrance and N. Knight showed that **diffusion** phenomena of aq. soln. of sodium aluminium sulphate corresponded with a large amount of dissociation. W. Voigt measured the **elasticity constants** of the crystals of potash-alum and found the elastic anisotropy to be small.

The coeff. of **thermal expansion** of potash-, rubidia-, cæsia-, and ammonia-alums can be calculated readily from the data by W. Spring[8] on the effect of temp. on the sp. gr. E. Wiedemann observed that potash-alum contracts when heated above 51·3° in a mercury dilatometer, and explained the phenomenon by assuming that the complex mol. dissociate into their constituent mol. E. N Ivanova showed that the alleged contraction is a mal-observation due to the slow filling of the interstices of alum by mercury. The **specific heat** of potash-alum between 15° and 22° was found by E. Baud to be 0·349; and between −188° and 18°, by J. Dewar, 0·256. W. Nernst and F. Schwers found the mol. ht. to be 165·66 at 183·5°, and 27·83 at −247·3°. K. Bindel found for 6·3, 16·6, and 39·4 per cent. soln. of potash-alum the respective sp. ht. 0·943, 0·860, and 0·714; and for 5·8, 15·5, and 37·4 per cent. soln. of ammonia-alum, respectively 0·942, 0·858, and 0·691.

T. Graham said that potash-alum loses three-fourths of its water of crystallization at 64·5°, and he accordingly represented it by the formula $K_2SO_4.Al_2(SO_4)_3.6H_2O+18H_2O$. K. Kraut found that the same proportion of water is lost when the salt is confined over conc. sulphuric acid for 180 days. W. Müller-Erzbach measured the **vapour pressure** of the crystals of soda-, potash-, and ammonia-alums, and from the loss of water by potash-alum confined over sulphuric acid of different conc., he inferred, like T. Graham, that 18 of the 24 mols of water are more loosely attached than the other six; with soda-alum, he found one-half the water is more loosely attached than the other half; and with ammonia-alum, nine mols are more loosely attached than the others. H. G. F. Schröder found all the water is lost in vacuo at 185°. G. F. Gerhardt found 20 mols of water are lost at 120°, and all at 200°, and at the same time the salt becomes sparingly soluble in water. S. Lupton said 23 mols of water are lost at 180°–190° from potash- and ammonia-alums; and, according to G. J. Mulder:

	40°	47°	56°	82°	101°	110°	172°	201°
Percentage loss H_2O .	2·7	9·6	27·2	29·6	34·2	37·4	42·8	44·5

J. W. Mallet found that finely powdered ammonia-alum confined over conc. sulphuric acid at 20°–27°, lost the following proportions of water in mols:

Mols H_2O lost .	1	2	3	4	5	6	7	8	9	10
Hours . .	75	78·5	78·5	90	96	122	155	170	182	231

and 11 mols in 282 hrs.; 12 mols in 459 hrs.; 13 mols in 744 hrs.; 14 mols in 1121 hrs.; and 19 mols in 9646 hrs. E. T. Erickson found that the mineral tschermigite loses three-fourths of its water at 105°, and nearly all at 200°; decomposition begins at 360°, and on ignition the total loss is 88·06 per cent. K. Kraut showed that all the water is lost when potash-alum is heated in a current of air at 100° for 120 hrs., and that there is no loss of sulphur trioxide, while the salt retains its faculty of readily dissolving in water. J. Juttke said that the loss of water in air begins at 34°, and at that temp. 5 mols of water are lost in 85 hrs.; at 42°, 11 mols; at 65°, 19 mols; at 91°, 19 mols; and at 100°, 24 mols. Hence no more water is lost between 65° and 91° than is lost at 65°. P. Zellner said that soda-alum begins to lose water at 40°–50°, and the crystals become turbid. J. M. Wadmore found that soda-alum loses about half its water at 50°, and A. Ure said all is lost at a red heat, and the residue is completely soluble in water. S. Macischevsky measured the vap. press. of soln. of ammonia-alum and of potash-alum, and found that each salt gave two curves intersecting in the case of the former at 82·7°, and in the case of the latter at 79·5°. These points represent a chemical change in these alums.

When the alums are heated, they melt in their water of crystallization; C. M. Marx found the **melting point** of potash-alum to be 92°; G. J. Mulder, 92·5; and W. A. Tilden, H. Erdmann, and J. Locke gave for the different alums:

	Na-	K-	NH_4-	Rb-	Cs-alum
M.p. (W. A. Tilden)	61°	84·5°	92°	99°	105°–106°
M.p. (H. Erdmann)	—	92·5°	—	105°.	120·5°
M.p. (J. Locke) . . .	63°	91°	95°	109°	122°

so that W. A. Tilden's results appear to be too low. E. Hart and H. B. Huselton found the m.p. of cæsium alum to be 117°. C. M. Marx observed the under-cooling of molten potash-alum. According to C. Hertwig, molten potash-alum at 100° becomes more and more viscid and finally solidifies to a clear vitreous mass; at 120°, the molten alum swells and loses water, and after 12 hrs. is converted into a porous mass containing 5 mols of water; even at 280°, the mass still retains one-half mol of water. A. Naumann said that potash-alum which has been kept at 78° for some time forms, when melted, a turbid liquid. H. Löwel, and A. Naumann heated potash-alum in a sealed tube at 100°, and the latter stated that the liquid becomes turbid, forming dehydrated alum, and the separated water hydrolyzes the salt, forming a basic potassium aluminium sulphate; at 200°, the product, according to H. Löwel, is $K_2SO_4.3Al_2(SO_4)_3$. According to E. Wiedemann, potash-alum expands regularly when heated up to 30°, when water begins to be given off; the salt melts at 90°; on cooling to the original temp., there is a contraction of 1·42 per cent., but ammonia-alum melts at 92°, and when cooled to its initial temp., the original volume is restored. H. Erdmann also found rubidia-alum at 205° melts to a clear liquid, then begins to boil, and forms the anhydrous salt; if the molten salt be cooled before it has lost water, it forms a sticky mass. When potash-alum is gradually heated to a temp. below redness, it loses water, swells up very much, and leaves a loose, friable, porous mass of dehydrated alum—the so-called *alumen ustum*, or *burnt alum*. At a white heat, the sulphuric acid is expelled from the aluminium sulphate, leaving a residue of alumina and potassium sulphate; if heated in a retort, the distillate has been called *spirit of alum*, which is a soln. of sulphurous and sulphuric acids. According to C. Brunner, at a certain period of the decomposition, potassium hydrosulphate can be detected in the residue. When ammonia-alum is similarly treated, alumina alone remains, the ammonium sulphate is volatilized. P. A. Favre and C. A. Valson found that the ammonium sulphate volatilizes with far greater difficulty than when alone.

G. Tammann found the **lowering of the vapour pressure** of water by ammonia alum for soln. of 10·97, 34·41, and 67·99 grms. of $(NH_4)_2SO_4.Al_2(SO_4)_3$ per 100 grms. of water to be respectively 10·9, 36·9, and 96·4 mm. G. J. Mulder found the **boiling point** of a soln. of 210·6 parts of potash-alum in 100 parts of water to be 111·9°; T. Griffiths found a soln. with 52 parts of potash-alum in 100 parts of water to boil at 104·5°, and G. T. Gerlach found for *w* grms. of potash-alum in 100 parts of water:

	0	7	107	296	615	971	2632	∞
Boiling point .	100	101°	102°	103°	104°	105°	106°	106·7°

M. Plessy gave 12·4 Cals. for the **heat of solution** of $KAl(SO_4)_2.5H_2O$, and −10·12 Cals. for $KAl(SO_4)_2.12H_2O$; for $NH_4Al(SO_4)_2.12H_2O$, the heat of soln. is −9·6 Cals. According to F. Rudorff, when 14 parts of potash-alum are mixed with 100 parts of water, the temp. can fall from 10·8° to 9·4°. H. C. Jones and E. Mackay measured the **lowering of the freezing points** of aq. soln. of the alums, and inferred that the alums in aq. soln. are almost completely broken down into their constituent salts in dil. soln., but not completely in more conc. soln. R. Dubrisay studied the temp. of miscibility of soln. of alkali and aluminium sulphates.

The **index of refraction** of crystals of soda-alum has been measured by C. Soret;[9] of potash-alum, by C. Soret, H. Dufet, A. Borel, A. Mühlheims, D. Brewster, F. Kohlrausch, J. Grailich, J. Stefan, and A. Fock; of ammonia-alum, by A. Borel,

J. Grailich, and C. Soret; and of rubidia- and cæsia-alums by C. Soret. The results by the last-named are indicated in Table VII. E. Forster calculated the sp. refraction of the mols. of water-free alum in aq. soln. to be 0·1809 at 24°. The **anomalous double refraction** of potash-alum has been studied by E. Reusch, E. Mallard, F. Klocke, R. Brauns, R. Krickmeyer, and F. Pockels; and of ammonia-alum, by F. Klocke. The refractive index of crystallizing soln. of potash- and ammonia-alums was measured by H. A. Miers and F. Isaac. E. Aschkinass found a small reflection band in the **ultra-red reflection spectrum** of potash-alum at 9·05μ; and W. W. Coblentz, a maximum at 9·1μ. The **ultra-red transmission spectrum** has water bands at 1·5μ and 2μ. W. Crookes studied the adsorption of heat rays from an electric arc by a sat. soln. of ammonia-alum 5 cms. thick, and found that a thermometer registered 170°, when it registered 197° if water alone was used. C. Schäfer and M. Schubert, S. B. Nicholson and E. Pettit, and L. Vegard and H. Schjelderup studied the ultra-red vibration frequencies of the alums, and concluded that any hypothesis which would distinguish the water of crystallization from water of constitution could not be reconciled with the observed relations between the high-frequency reflection spectra. The removal of the water of crystallization is necessarily accompanied by the destruction of that structure which is characteristic of the hydrated salt. An aq. soln. of alum permits the passage of all visible rays but of only a few ultra-red rays; a soln. of iodine in carbon disulphide cuts off all visible light rays and is permeable to ultra-red rays. T. E. Aurén found the mol. absorption of X-rays by alum to be the sum of the at. absorptions of the constituent elements.

TABLE VII.—REFRACTIVE INDICES OF THE ALUMS.

λ	Na-alum 17°–18°	K-alum 14°–17°	NH_4-alum 15°–21°	Rb-alum 7°–21°	Cs-alum 15°–25
G(431)	1·44804	1·46854	1·46923	1·46618	1·46821
F(486)	1·44412	1·46420	1·46481	1·46192	1·46386
b(518)	1·44231	1·46229	1·46288	1·45999	1·46203
E(527)	1·44185	1·46168	1·46234	1·45955	1·46141
D(589)	1·43884	1·45862	1·45939	1·45660	1·45856
C(656)	1·43653	1·45630	1·45693	1·45417	1·45618
B(686)	1·43563	1·45527	1·45599	1·45328	1·45517
a(718)	1·43492	1·45463	1·45509	1·45232	1·45437

F. S. Svenson[10] measured the **electrical conductivity** of aq. soln. of soda-, potash-, and ammonia-alums. H. C. Jones and co-workers found for the mol. conductivity, μ, of potash- and ammonia-alums for soln. with a mol of the salt in v litres of water:

v		4	8	32	218	512	1024	2048	4096
K	μ at 0°	—	78·9	101·2	127·6	158·8	177·8	197·5	218·8
	μ at 65°	196·1	240·6	317·4	426·2	557·1	—	769·4	—
NH_4	μ at 0°	—	80·0	102·5	130·1	162·2	181·0	201·8	224·2
	μ at 65°	—	236·5	—	—	578·5		831·5	—

The alums, in dil. soln., have a conductivity which is almost exactly the mean of the conductivities of their constituents, from which it follows that the complex alum mols. are broken down completely in such soln. into the mols. of the simpler sulphates, and that these simpler mols. ionize as if alone, barring the effect on the ionization produced when the soln. are not isohydric. In conc. soln., the alums show a conductivity less than the mean of the conductivities of their constituents. The difference becomes more marked as the conc. increases, and is of the same order as that observed for other double sulphates. It is much greater than that found in the case of mixtures of sulphates incapable of yielding a double salt. This must be regarded as evidence that the alums are partially undecomposed into the constituent mols. in such soln., or that the ionization into the simple ions into which the single sulphate break down is not complete. This is confirmed by the f.p. determinations. J. F. Daniell and W. A. Miller made some observations on the **transport numbers** of the alums in aq. soln. J. Curie, H. Starke, and W. Schmidt measured the **dielectric constant** of potash-alum; for $\lambda=\infty$, this constant is 6·67, and for $\lambda=75$ cms., 6·25.

L. Kralovansky[11] said that the **solubility** of lithia-alum in *water* at ordinary temp. is 4·17 grms. of the salt in 100 parts of cold water and 115 grms. of the salt in 100 parts of hot water. P. Zellner said that 100 parts of water at 13° dissolve 46·7 parts of the salt, and 100 parts of the salt if the water is boiling. A. Ure said that 100 parts of water at 15·5° dissolve 110 parts of soda-alum. W. R. Smith found for the percentage solubility of soda-alum:

	10°	15°	20°	25°	30
Na-alum . . .	26·9	27·9	29·0	30·1	31·4

There is a transition temp. about 30° with soda-alum in contact with its sat. soln. Above 28°, said E. Augé, the soln. seems to lose its faculty of crystallizing. J. M. Wadmore, E. Augé, and W. A. Tilden have also made observations on the solubility of soda-alum in water. E. Augé said that at temp. approaching 0° hydrated sodium sulphate crystallizes from the aq. soln. The solubility of potash-alum has been measured by R. Brandes, J. B. Richter, J. Locke, L. Marino, A. B. Poggiale, J. Redtenbacher, the Earl of Berkeley, etc. The best representative values for the percentage solubilities are:

	0°	15°	30	45°	60°	m.p.
K-alum. . .	2·87	4·80	7·74	12·48	19·85	54·45

To these G. J. Mulder added: 100°, 60·63; 110°, 66·67; and 111·9°, 67·81 per cent. in which the solid phase is $KAl(SO_4)_2.nH_2O$. The Earl of Berkeley found that a solid separated from soln. at about 68°. C. J. B. Karsten said that potash-alum is almost insoluble in soln. of aluminium sulphate. C. Reuss, and L. Marino made observations on this subject; expressing the results in mols of salt per 1000 mols of water, the latter found, with alum and aluminium sulphate as solid phases:

	0°	20°	35°	50°	65°	77°
$Al_2(SO_4)_3$ . .	6·1	15·1	24·1	33·5	43·1	50·5 mols.
K_2SO_4 . .	2·3	3·1	3·6	6·1	12·3	18·9 ,,

and with alum and potassium sulphate as solid phases, L. Marino found:

	0°	10°	30°	40°	60°	80°
$Al_2(SO_4)_3$ . .	0·1	0·5	1·0	1·9	6·7	28·1 mols.
K_2SO_4 . .	7·8	9·9	15·2	16·8	34·6	53·4 ,,

G. J. Mulder found that at 10°, 100 parts of water sat. with potassium sulphate dissolved 0·86 part of potash-alum. F. P. Venable found that the solubility of potash-alum is reduced by the presence of soda-alum; the amounts in grams of potash-alum dissolved by soln. containing the following amounts in grams of soda-alum, at 25°, are:

Na-alum . .	4·8	10·0	12·1	15·4	21·1	33·7	55·6	76·7
K-alum . .	7·8	6·1	5·7	5·3	4·7	3·8	2·7	1·7

A. Fock measured the effect of thalia-alum on the solubility of potash-alum; and C. von Hauer, the effect of chrome-alum and of ferric-alum; and G. J. Mulder, the effect of magnesium sulphate. C. J. B. Karsten found that potash-alum crystallizes unchanged from its soln. in presence of potassium nitrate or chloride. According to P. L. Geiger, if burnt alum be quenched in water it remains undissolved for many months, but if it has been exposed to air for a fortnight, it regains its peculiar taste, and dissolves with ease. The solubility of potash-alum in *alcohol* is very small.

The solubilities of rubidia-alum and cæsia-alum have been measured by C. Setterberg, J. Redtenbacher, E. Hart and H. B. Huselton, the Earl of Berkeley, and F. Godeffroy. The best representative values for the percentage solubilities are:

	0°	15°	30°	45°	60°	80°	100·4°	m.p.
Rb-alum . .	0·715	1·25	2·15	3·85	6·89	17·77	—	58·5
Cs-alum . .	0·21	0·35	0·60	1·04	1·96	5·21	18·60	62·00

The Earl of Berkeley found that a solid separated from the soln. of rubidia-alum at 80°. The solubility of ammonia-alum was determined by F. Pohl, A. B. Poggiale, G. J. Mulder, and J. Locke. The best representative values for the percentage solubility are :

	0°	10°	20°	40°	60°	80°	m.p.
NH_4-alum . .	2·53	4·31	6·19	11·00	17·40	26·00	52·20

and G. J. Mulder added that at 110·6°, the solubility is 67·50 per cent. with a hydrate $NH_4Al(SO_4).nH_2O$ as solid phase. According to F. Guthrie, the eutectic or cryohydric temp. is −0·20° with 4·3 per cent. of dehydrated alum—this last number is too large. F. Rüdorff measured the effect of aluminium and ammonium sulphates on the solubility of ammonia-alum. By raising the *pressure* up to 400 atm., E. von Stackelberg found that the potash-alum content of a gram of the soln. was raised from 0·115 to 0·142 grm.

Ammonia- and potash-alums have an indescribable taste, for they are sour and yet sweet. O. Schumann found that when potash-alum is heated in a stream of **hydrogen,** sulphur dioxide and water are formed and the residue contains a little sulphate but no sulphide, and is but partially soluble in hydrochloric acid. E. Augé stated that soda-alum is only very slightly efflorescent in **air,** and may be kept several months without alteration. Statements to the contrary are said to be based on observations with the impure salt. When crystals of potash-alum are exposed to the air, they become an opaque-white superficially, some ammonia is absorbed from the air, and a basic sulphate formed. According to K. Kraut, alum which has lost 18 mols of water over conc. sulphuric acid absorbs the lost water from the atm. during 3 months' exposure, while H. von Blücher said that burnt alum absorbed 18 mols of water from the atm. after 47 days' exposure to air in summer, and more water continues to be absorbed. The soln. reddens litmus. T. Graham[12] F. Rüdorff, and C. L. Parsons and W. W. Evans showed by diffusion experiments that the two sulphates can be separated by diffusion, and J. C. G. de Marignac concluded that the complex salt is formed only at the moment of crystallization. G. T. Gerlach pointed out that the slight volume changes which occur on mixing the component salts indicated that some combination does occur in soln. While H. C. Jones and E. Mackay showed by f.p. and conductivity measurements that dil. soln. of alum in **water** behave like soln. of the mixed sulphates; in conc. soln. alone are there signs of the formation of complexes. If this be so, the liberated aluminium sulphate in dil. aq. soln. of alum should be more or less hydrolyzed by water as in the case of aq. soln. of aluminium sulphate alone (*q.v.*), except possibly some protective action by the alkali sulphate. C. R. C. Tichborne found aq. soln. of potash-alum decompose at about 100° with the separation of insoluble flecks which can be recognized by illuminating the soln. The Earl of Berkeley also noted separations with aq. soln. of potash-alum at 68°, and with rubidia-alum at 80°. A. Naumann said a basic aluminium sulphate separates as a white precipitate when aq. soln. of alum are boiled. It was found that with pure alum soln. the decomposition was most rapid at first, gradually becoming less for equal intervals of time, so that a state of equilibrium in the liquid was reached only after a very long time. Dilution of the soln. favoured decomposition. Free sulphuric acid, added to alum soln., prevented the decomposition, partially or entirely, according to the amount added. Neutral potassium sulphate, on the contrary, expedited the decomposition—*vide* basic aluminium sulphates. A. Mitscherlich obtained löwigite by heating potash-alum with water in a sealed tube at 170°–230°. According to R. Willstätter, alum can take up **hydrogen peroxide** of crystallization.

According to J. W. Thomas, **hydrogen chloride** is without action on dehydrated potash-alum. In studying the effect of **hydrochloric acid** on the crystalline form of potash-alum (*q.v.*), P. A. Schemjatschensky sometimes obtained crystals of complex *potassium chlorosulphatoaluminate*, $6\{KAl(SO_4)_2.12H_2O\}.K_2SO_4.8KCl.6AlCl_3$. J. B. Richter noted that when potash-alum is heated with **potassium or sodium chloride,** hydrogen chloride is set free; while if a conc. soln. of the alum is boiled with potassium chloride, sodium chloride, or **ammonium chloride,** a sparingly soluble basic sulphate is precipitated. These reactions were also discussed by R. von Wagner, and F. J. Knapp. J. B. Richter also observed that a mixed soln. of alum, sodium chloride, and potassium nitrate dissolves gold. When crystals of potash-alum are kept under cold conc. **sulphuric acid** for a fortnight, a white pasty mass is formed which when treated with water becomes hot, and when dissolved in boiling water, yields, on cooling, octahedral crystals of $K_2SO_4.Al_2(SO_4).14H_2O$, according to C. Hertwig; or $K_2SO_4.Al_2(SO_4)_3.24H_2O$, *according to* W. Heintz. Boiling sulphuric acid converts alum into an insoluble white powder which, according to C. F. Gerhardt, is converted by water into crystals of ordinary alum, but, according to A. Laurent, into crystals of an acid sulphate, $Al_2(SO_4)_3.H_2SO_4$ W. F. Salm-Horstmar said that if alumina be melted with **potassium hydrosulphate,** and the cold mass extracted with hot water, small six-sided crystals of a product approximating to water-free alum are produced. When burnt alum is heated with **carbon,** a pyrophoric mixture containing alumina and potassium sulphide is formed. J. Thomsen found that the thermal value of the reaction between **potassium hydroxide** and potash-alum is 30·53 Cals., and he assumed, in consequence, that $Al_2(SO_4)_3+6KOH=3K_2SO_4+2Al(OH)_3+30{\cdot}53$ Cals., but A. V. E. Young believes that the deduction is invalidated by the significant side reactions which occur. L. B. Miller studied the fractional precipitation of alumina from soln. of alum—*vide* aluminium hydroxide. N. R. Dhar and co-workers found that **copper hydroxide** precipitates aluminium hydroxide from a soln. of potash-alum, and while copper goes into soln. some is retained by the precipitate. J. Löwe said that **zinc** in contact with platinum dipped in an aq. soln. of alum furnishes hydrogen, and a basic aluminium sulphate.

Many dyes are capable of combining directly with the fibre of the cloth to be dyed in such a way that the colouring matter is not removed by water and soap; in other cases, the fibres can be permanently dyed by previously treating them with aluminium hydroxide. The fibre absorbs the hydroxide from aq. soln. of aluminium salts—the so-called *red-liquor, mordant d'alumine*, or *Rothbeize*—and the dye can unite with the aluminium hydroxide to form insoluble lakes so that the aluminium hydroxide is an intermediary agent or *mordant* enabling the fibre to be dyed. W. W. Paddon[13] regards the effect of alum on fibres to be strictly an adsorption phenomenon in which both sulphuric acid and alumina are involved; and not a chemical union with the fibre as advocated by E. Knecht.

Lower hydrated forms of alum.—The *dodecahydrate* of sodium aluminium sulphate has been previously described in connection with soda-alum. According to L. Marino,[14] if a supersaturated soln. of potash-alum in its own weight of water at 40° be seeded with crystals of ammonium thallic sulphate, $(NH_4)_2SO_4.Tl_2(SO_4)_3.8H_2O$, crystals of the *heptahydrate*, $K_2SO_4.Al_2(SO_4)_3.14H_2O$, are formed which readily pass into ordinary alum. P. T. Cleve's analysis of the sodium aluminium sulphate found on St. Barth (West India) corresponds with the *hexahydrate*, $Na_2SO_4.Al_2(SO_4)_3.12H_2O$. L. Marino reported a *tetrahydrate*, $K_2SO_4.Al_2(SO_4)_3.8H_2O$, to be formed in needle-like crystals by holding molten potash-alum at 85°-86°, and as soon as crystals begin to form, by sealing the mass in a tube to prevent the loss of water, and holding the temp. at 95°. He also made the *tetrahydrate* $(NH_4)_2SO_4.Al_2(SO_4)_3.8H_2O$ in a similar way.

Basic alums.—According to A. Mitscherlich,[15] when an alkali is gradually added to an aq. soln. of alum, the precipitate produced redissolves on stirring until a certain proportion of alkali has been added, any further addition produces a permanent precipitate. The soln. which is on the point of giving a precipitate is called in commerce *neutral alum*, and it is used in mordanting cloth for dyeing. If the soln.

is heated to 40°, a precipitate is formed corresponding with **potassium aluminium hydroxysulphate,** $K_2SO_4.Al_2(SO_4)_3.4Al(OH)_3$, or *potassium hexahydroxy-disulphato-trialuminate*, $KAl_3(SO_4)_2(OH)_6$, or $K[Al(OH)_2]_3(SO_4)_2.3H_2O$. This compound is represented in nature by the mineral *alunite*. A. Mitscherlich obtained it in a crystalline form by heating the neutral alum in a sealed tube at 230°. He also made a *soda-alunite*—**sodium aluminium hydroxysulphate**—and an *ammonia-alunite*—**ammonium aluminium hydroxysulphate**—in a similar way. The *alumen de Tolpha* mentioned in connection with the history of aluminium; the *Alaunstein* of A. G. Werner; the *alun de Rome* of R. J. Haüy; the *Alaunspath* of A. Breithaupt; or the *aluminilite* of J. C. Delamétheric, was called *alunite* by F. S. Beudant, and this term has remained. Analyses were made by L. Cordier, A. Mitscherlich, C. F. Rammelsberg, M. Sauvage, F. Fridau, J. Gautier-Lacroze, etc. The idealized summary of the analyses is $K_2SO_4.Al_2(SO_4)_3.4Al(OH)_3$. The mineral occurs at Tolfa (Italy), Montioni (Tuscany), Muzsai and Bereghszasz (Hungary), Milo, Argentiera, and Nevis (Grecian Archipelago), Mont Dore (France), etc. It is supposed to have been formed by the action of volcanic gases containing sulphur dioxide on felspathic trachytes, etc. The rhombohedral crystals belong to the trigonal system, and have the axial ratio $a:c=1:1·245$, and $\alpha=89° 14'$; the sp. gr. is 3·15 to 3·26; H. Bowley gave 2·65 for the sp. gr., and 1·58 for the index of refraction; the double refraction is negative. Alunite loses water at 350°, and at a dull red heat, about 530°, it gives off water and sulphur trioxide; after calcination in the blowpipe flame, water extracts potassium sulphate and leaves alumina. H. Bowley saw that at 300° there is no decomposition; at 400°, 4·5 mols. of water are lost; at 500°, the remaining 1·5 mols. are expelled; at 800°, dissociation into potassium sulphate, alumina, sulphur trioxide, and water is complete; and at 960°, potassium aluminate is formed. H. Bowley found alunite to be sparingly soluble in water. Alunite is not dissolved by boiling conc. hydrochloric acid; but it is decomposed by that acid in a sealed tube at 200°, and if pre-calcined, it is decomposed by that acid. It is soluble in boiling sulphuric acid of sp. gr. 1·854, but it dissolves more quickly in dil. acid. H. Bowley said that alunite is readily soluble in warm dil. soln. of hydrofluoric acid, sodium or potassium hydroxide, sodium carbonate, and hot conc. sulphuric acid. It is fairly readily attacked by a soln. of calcium hydroxide or carbonate. He also described a *soda-alunite*.

A. Mitscherlich also obtained a kind of hydrated alunite, $K_2SO_4.Al_2(SO_4)_3.4Al(OH)_3.3H_2O$, or $K[Al(OH)_2]_3(SO_4)_2.1\frac{1}{2}H_2O$, by heating a soln. of potassium sulphate with less aluminium sulphate than is needed for the preparation of alunite. By the action of zinc, or of alkali hydroxides or carbonates on soln. of potash-alum, H. Debray, W. Crum, C. Rössler, A. Riffault, and L. F. Bley obtained precipitates which approximated in composition to the product just indicated. It is represented by the mineral *löwigite*, found in compact masses associated with alunite, and at Tabrze (Upper Silesia); it has been described by A. Mitscherlich, P. Berthier, C. F. Rammelsberg, F. Römer, C. Lowig, etc. A similar basic ammonium salt was obtained by A. Maus, A. Riffault, and A. Mitscherlich by using aq. ammonia in place of potash-lye.

The blue hair-like crystals from Moldawa (Rumania), analyzed by J. Percy,[16] and by F. A. Genth, correspond with $2Al_2O_3.9CuO.3SO_3.21H_2O$, or with $Al_2O_3.4CuO.SO_3.8H_2O$. It was called *lettsomite*—after W. G. Lettsom; E. F. Glocker called it *cyanotrichite*—κύανος, blue; θρίξ, hair; and it has also been called *velvet copper ore*, or *cuivre velouté*. The mineral *woodwardite* from Cornwall was analyzed by A. H. Church, R. Warrington, and F. Pisani, and it corresponds with $11CuO.9·6Al_2O_3.9SO_3.23H_2O$. There is nothing to show the chemical nature of these products, and whether or not they represent *copper sulphato-aluminates*.

G. Arth[17] obtained fine acicular crystals on allowing a soln. of barium aluminate and calcium sulphate to stand for 24 hrs. The analysis corresponded with $CaO : Al_2O_3 : SO_4=5·76 : 1 : 2·67$—say $6 : 1 : 3$ with nH_2O. O. Rebuffat indicated the formation of *calcium sulphato-aluminate*, $11CaO.2Al_2O_3.5SO_3.52H_2O$, by the action of calcium sulphate and hydroxide on calcium aluminate. He also discussed the action of sea-water on this product and its bearing on Portland cement. A. A. Klein and A. J. Phillips have also discussed the calcium sulphato-aluminates; but they are not well enough defined to be recognized as chemical individuals. For $3CaO.3CaSO_4.Al_2O_3.30H_2O$, *vide* calcium aluminate.

There are a number of double sulphates of the type $MSO_4.Al_2(SO_4)_3.24H_2O$, in which M may be Mg, Zn, Fe'', or Mn. They are called **pseudo-alums,** and they are not isomorphous with ordinary alums. Very little is known about the pseudo-alums, and it is even doubtful if they have $24H_2O$. The so-called *magnesia-alum* is represented by the mineral *pickeringite*—named after J. Pickering—found in acicular crystals, fibrous masses, or efflorescences on shales near Iquique (Peru), Nova Scotia, Island of Negros, etc. It is probably formed by the action on the shale of decomposing pyrites. Analyses were made by H. Schulze,[18] D. L. Brackenbusch, E. Goldsmith, etc. R. J. Kane assigned to it the formula $MgSO_4.Al_2(SO_4)_3.24H_2O$, but, according to A. Hayes, and H. How, the analyses correspond with **magnesium aluminium sulphate,** $MgSO_4.Al_2(SO_4)_3.22H_2O$, or *magnesium tetrasulphato-aluminate*, $MgAl_2(SO_4)_4.22H_2O$.

Part of the magnesium in magnesia-alum may be replaced by manganese to form what E. F. Glocker called *apjohnite*. J. Apjohn called it *manganese-alum*. Analyses were made by F. Stromeyer, J. Apjohn, J. L. Smith, G. A. Kenngott, L. D. Gale, etc. A variety from Alcaparossa, Chili, containing some soda-alum was called *stüvenite*—after E. Stüven—by L. Darapsky; and a related variety from Cerros Pintados, Chili, was called *sesquimagnesia alum*, $1\frac{1}{2}MgSO_4.Al_2(SO_4)_3.26\frac{1}{2}H_2O$, by L. Darapsky. A variety from Sonoma Co., California, was called *sonomaite*—by E. Goldsmith. The composition approximated to $3MgSO_4.Al_2(SO_4)_3$ $33H_2O$. C. Doelter described a variety from S. Antao, one of the Cape Verde Islands, which he called *dumreicherite*—after A. von Dumreicher. Its composition was $4MgSO_4.Al_2(SO_4)_3.36H_2O$. L. Darapsky obtained a variety with the composition $6MgSO_4.Al_2(SO_4)_3.54H_2O$, from Pampa de Aroma, Chili, and he called it *aromite*. A similar mineral was obtained from Copiapo, Chili. G. Roster found a mineral which he named *picroallumogene*, and hence also *picroallumogin*, and *picralluminite*, at Vignoria, Island of Elba. The analysis corresponds with $2MgSO_4.Al_2(SO_4)_3.28H_4O$. Other analyses agree with $3MgSO_4.Al_2(SO_4)_3.33H_2O$.

C. Klauer obtained a product with the composition $3MgSO_4.Al_2(SO_4)_3.36H_2O$ by allowing a soln. of magnesium and aluminium sulphates in dil. sulphuric acid to evaporate spontaneously. R. J. Kane reported the formation of a *zinc-alum*, **zinc aluminium sulphate,** $ZnSO_4.Al_2(SO_4)_3.24H_2O$, by crystallization from a soln. of the components. E. Bertrand and A. Damour found hexagonal plates of a basic zinc aluminium sulphate, $12Al(OH)_3.Al_2(SO_4)_3.2\{6Zn(OH)_2.ZnSO_4\}.12H_2O$, or $Al_6Zn_6S_2O_{21}.18H_2O$, in the zinc mines of Laurium, Greece; they named the mineral *zincaluminite*. The sp. gr. was 2·26, and the hardness 2·5–5·3.

§ 21. Aluminium Carbonates

According to F. Scheermesser,[1] freshly prepared aluminium hydroxide dried in air absorbs carbon dioxide, for when the product heated to 140°, 986–1480 vols. of this gas are dislodged. P. R. Jourdain assumed that the carbon dioxide which he obtained by heating in vacuo the product of the oxidation of aluminium amalgam in air, showed that some aluminium carbonate is formed. N. T. de Saussure stated that aluminium hydroxide is partially soluble in an aq. soln. of carbonic acid, and is reprecipitated on warming the soln. or exposing it to air. *Au contraire*, C. Langlois found that if *freshly precipitated aluminium hydroxide be suspended in water*, it does not dissolve during the passage of carbon dioxide, but gas is absorbed by the solid.

In 1801, N. T. de Saussure stated that when an alkali carbonate is added to a soln. of an aluminium salt, the precipitate is not, as might be anticipated, **aluminium carbonate,** $Al_2(CO_3)_3$, but rather a compound of alumina with a small quantity of the alkali carbonate. J. Davy observed no difference in the effect of water, and of water sat. with carbon dioxide under press., upon alumina. J. J. Berzelius noted that the aluminium hydroxide precipitated by potassium carbonate cannot be washed free from the latter salt, and he doubted the existence of an aluminium carbonate. The effervescence with acid is attributed to presence of alkali carbonate. H. Rose found that the carbon dioxide in the precipitated carbonate corresponded with the adsorbed alkali. P. N. Raikow found freshly precipitated aluminium hydroxide does not absorb carbon dioxide, and this agrees with the measurements of the press. of carbon dioxide over aluminium hydroxide. G. Magnus pointed out that if a soln. of aluminium hydroxide in a hot soln. of potassium carbonate be cooled some aluminium hydroxide is precipitated and some is retained in soln., and can be precipitated by hydrochloric acid or by ammonium carbonate. L. F. Bley stated that either a basic carbonate or a basic double carbonate is formed when an excess of alkali carbonate acts on a soln. of alum or of aluminium sulphate. In many cases, the precipitate contains a carbonate although it is quite free from alkali carbonate. C. Langlois said with respect to the precipitate obtained by adding an alkali carbonate to an aluminium salt:

> It is generally believed that this precipitate is nothing but alumina, still retaining a little alkali carbonate to which is due the effervescence with acids. . . . By washing the precipitate with a sufficient quantity of water, it can be obtained entirely free from alkaline salt, and it then continues to effervesce, which proves that a part of the alumina remains combined with carbonic acid. A very basic compound of carbonic acid and aluminium hydroxide is unquestionably produced. This compound is destroyed at a temp. which does not exceed 100°.

J. Barratt said that when an aluminium salt is precipitated by an alkaline carbonate, no aluminium carbonate is formed; but several more or less indefinite, basic aluminium carbonates have been described by A. Gawalowsky, T. Parkman, J. S. Muspratt and J. Danson, R. Phillips, V. Urbain and M. Renoul, K. Seubert and M. Elten, W. C. Day, etc.—as precipitates when an alkali or ammonium carbonate is added to a soln. of an aluminium salt. The analyses are so discordant, that the products obtained vary in composition with the basicity of the acid contained in the aluminium salt, with the conditions under which the precipitate is formed; and with the amount of washing to which the precipitate has been subjected. The products represent different stages in the hydrolysis of aluminium carbonate, and are mixtures of the undecomposed aluminium carbonate or of a basic carbonate and the hydroxide. E. Schlumberger obtained what he regarded as $\{Al_2(OH)_5\}_2CO_3.H_2O$, by the action of a large excess of sodium carbonate on aluminium salts of the monobasic acids, or of carbon dioxide on cold soln. of alkali aluminates.

L. F. Bley showed that the precipitate obtained by adding ammonium carbonate to a soln. of potash-alum often contains ammonia; H. Rose regarded it as $(NH_4)_2O.Al_2O_3.2CO_2.4H_2O$; and M. Barth said that the precipitate obtained by adding a soln. of aluminium chloride to an excess of a cold soln. of ammonium carbonate is a mixture of a double **ammonium aluminium carbonate** with either aluminium hydroxide or carbonate. According to C. Löwig, when a soln. of an alkali aluminate is treated with alkali hydrocarbonate or free carbon dioxide, aluminium hydroxide and alkali carbonate are formed; but by allowing the soln. of alkali aluminate to flow into a soln. of alkali hydrocarbonate, with the simultaneous introduction of carbon dioxide, a **potassium aluminium carbonate** is formed with the composition $K_2O.Al_2O_3.2CO_2.5H_2O$ when dried at 80°. If the use of carbon dioxide be omitted, the precipitate is a hard horny mass. A. Ditte reported the basic double carbonate, $3K_2O.2Al_2O_3.5CO_2$, to be formed when a soln. of potassium carbonate is added to one of potassium aluminate until the precipitate persists when the soln. is agitated. C. Löwig made **sodium aluminium carbonate,** $Na_2O.Al_2O_3.2CO_2.nH_2O$, by a process similar to that which he employed for the potassium salt. L. F. Bley obtained a basic double carbonate, $2Na_2O.Al_2O_3.3CO_2.23H_2O$, by adding an excess of sodium sesquicarbonate to a boiling soln. of alum. W. C. Day also prepared this salt. The rare mineral *dawsonite*, analyzed by B. J. Harrington, G. Friedel, and M. Chaper, has a composition corresponding with $NaAl(OH)_2CO_3$, mixed with some impurities, chiefly calcite. The monoclinic crystals were examined by A. des Cloizeaux; their sp. gr. is 2·40.

According to J. H. and G. Gladstone, the hydrated aluminosilicate, *collyrite*, found at Hove (Sussex), is associated with a mineral called *hovite* containing calcium carbonate with a sufficient excess of carbon dioxide to convert all the lime into hydrocarbonate, $Ca(HCO_3)_2$, but this hypothesis is considered to be unsatisfactory in view of the known solubility of calcium hydrocarbonate and its instability in the solid state; it is therefore suggested that the excess of carbon dioxide is either combined as a hydrated **calcium aluminium carbonate,** or it replaces part of the silica in collyrite. W. C. Day believes hovite to be a basic calcium aluminium carbonate. C. Löwig prepared a basic **magnesium aluminium carbonate,** $2Al(OH)_3.MgCO_3$, by slowly adding a soln. of magnesium hydrocarbonate to a soln. of an alkali aluminate, or conversely. M. Crespi and E. Moles made complexes with the camphor group.

§ 22. The Aluminium Nitrates

C. F. Wenzel[1] attempted to neutralize alumina with nitric acid, and concluded that "the ratio of alumina to the most conc. nitric acid is nearly as 349 : 240," showing that he had only partially saturated the base. Aluminium hydroxide or the metal dissolves in nitric acid and, as shown by W. F. Salm-Horstmar,

J. M. Ordway, T. B. Stillmann, etc., the acid soln. furnishes crystals of the *enneahydrate* of **aluminium nitrate,** $Al(NO_3)_3.9H_2O$, in rhombic prisms or plates. If the soln. be evaporated, and not kept strongly acid, a tenacious gum-like mass is produced instead of crystals. J. J. Hood made a soln. of the normal nitrate by double decomposition between aluminium sulphate and potassium, ammonium, calcium, or barium nitrate. According to R. Seligman and P. Williams, when aluminium is left in contact with nitric acid of sp. gr. 1·42, at 20°, the metal slowly dissolves, *and the acid becomes saturated with aluminium nitrate, which deposits in large crystals until the aluminium has all dissolved, or the acid has been exhausted.* In all soln. with acid of 1·42 sp. gr., except those with carbamide, an unstable *hexahydrate*, $Al(NO_3)_3.6H_2O$, is first formed. The hexahydrate is alone stable in nitric acid of sp. gr. 1·5, and in nitric acid of sp gr. 1·42 it is soon transformed into the enneahydrate. It was shown qualitatively that the hexahydrate is more soluble than the enneahydrate. M. Z. Jovitschitsch prepared crystals of the *hemipentadecahydrate*, $Al(NO_3)_3.7\frac{1}{2}H_2O$, by the action of conc. nitric acid on calcined alumina; and R. Seligman showed that either this hydrate or an *octohydrate*, $Al(NO_3)_3.8H_2O$, is the stable form in an acid of sp. gr. 1·46. A. Ditte also reported the formation of a *dihydrate*, $Al(NO_3)_3.2H_2O$. In his study of the ternary system, $HNO_3-Al(NO_3)_3-H_2O$, at 25°, K. Inamura found only three stable hydrates. The *enneahydrate*, $Al(NO_3)_3.9H_2O$, is stable in 73 per cent. nitric acid of sp. gr. 1·435, or more dil. acids; the *octohydrate*, $Al(NO_3)_3.8H_2O$, is stable in 73–81 per cent. nitric acid of sp. gr. 1·1435 1·1463; and the *hexahydrate*, $Al(NO_3)_3.6H_2O$, is stable in nitric acid more conc. than 81 per cent. HNO_3. The results are plotted in Fig. 68; a selection of the percentage numbers is as follows:

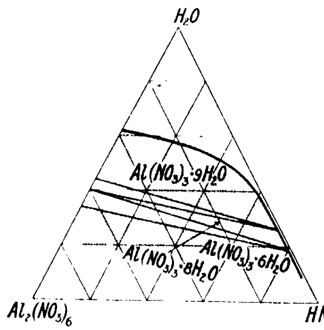

FIG. 68. Ternary System, $Al(NO_3)_3$ HNO_3 H_2O, at 25°.

$Al_2(NO_3)_6$ . .	39·04	34·24	25·32	17·57	5·05	1·25	0·24	0·21
HNO_3 . .	0·15	6·15	17·15	28·65	47·08	72·06	80·58	88·86
H_2O . . .	60·81	59·61	57·53	53·78	47·87	26·69	19·18	10·93
Solid phase	$Al(NO_3)_3$ $9H_2O$					$8H_2O$	$6H_2O$	

According to A. S Eakle, the enneahydrate deposited from soln. containing periodate, appears in thin plates belonging to the rhombic system with axial ratios $a:b:c=0·8925:1:1·0202$; while some prismatic crystals examined by C. Soret, and belonging to the monoclinic system, had the axial ratios $a:b:c=1·13398:1:1·91913$, and $\beta=131°\ 36'$ according to N. I. Surgunoff, these monoclinic crystals are isomorphous with the corresponding ferric salt. P. W. Bridgman examined aluminium nitrate up to 12,000 kgrms. press., and at 20°, 100°, and 200°, but observed no allotropic changes. The salt decomposed into a brownish mass. K. Jauch found the sp. ht. of soln. with N eq. of aluminium nitrate per litre to be:

N . . .	0·5	1·0	2·0	3·0	4·0	5·0
Sp. ht. . .	0·9563	0·9127	0·8546	0 8008	0·7504	0·7140

According to J. M. Ordway, after the enneahydrate has been heated 36 hrs. on a water-bath, there remains the eq. of $Al(NO_3)_3.1\frac{1}{2}H_2O$. A. Ditte found that if the crystals are heated until red vapours begin to be evolved, and the residue be dissolved in monohydrated nitric acid, white needle-like crystals of hydrated aluminium nitrate appear. According to T. Schlösing, the crystals melt at 73°, and form a colourless liquid which becomes crystalline when cooled; at 140°, aluminium hydroxide is produced, $Al(OH)_3.1\frac{1}{2}H_2O$; and at 200°-250°, said H. St. C. Deville, granular alumina remains. A method of separating alumina from lime and magnesia has been based on the fact that the nitrates of the two last-named bases resist temp. at which aluminium nitrate is decomposed. According to J. M. Ordway, a mixture of equal parts of crystals of aluminium nitrate and ammonium hydrocarbonate acts as a freezing mixture, lowering the temp. from +10·5° to −23·3°. J. R. Collins measured the ultra-red spectrum of aq. soln. of the nitrate. H. C. Jones and F. H. Getman measured the electrical conductivity and f.p. of the soln. According to H. C. Jones, the mol. electrical conductivity, μ, of soln. with a mol of the nitrate in v litres, at 0°, is:

v	4	8	32	128	512	1024	4096
μ at 0°	102·82	115·67	126·32	156·18	166·97	173·45	187·89
μ at 65°	338·6	393·6	487·3	583·9	685·9	750·5	908·2

A. Heydweiller gave the sp. gr. and electrical conductivity of soln. of aluminium nitrate. The percentage degrees of ionization, a, calculated from these data are:

v	4	8	32	128	512	1024	4096
a at 0°	54·7	61·6	72·5	83·1	88·9	92·3	100·0
a at 65°	37·3	43·4	53·6	64·3	75·5	82·6	100·0

These results are based on the assumption that no hydrolysis occurs. J. Walker and E. Aston computed that a $\frac{1}{2}N$-soln. at 80° is hydrolyzed to the extent of 0·7 per cent. H. C. Jones also computed the temp. coeff. of the electrical conductivity of the soln.

The crystals are deliquescent in moist air. The salt dissolves readily in water and nitric acid. L. H. Milligan found the solubility of the enneahydrate in nitric acid of different conc. and temp. Representing conc. in per cent. by weight, and sp. gr. at $\theta°/20°$:

	0·4°–0·5°		19·8°–20°		40°		60°	
HNO_3	19·75	50·65	15·45	71·35	11·95	64·50	4·93	32·65
$Al(NO_3)_3$	19·65	1·50	27·10	0·74	34·6	4·15	44·30	29·10
Sp. gr.	1·311	1·335	1·350	1·415	1·399	1·400	1·459	1·461

The salt is readily soluble in alcohol. W. Eidmann also found the nitrate to be soluble in acetone. The aq. soln. has an acid taste, and reddens blue litmus. According to J. J. Berzelius, aq. ammonia precipitates a gelatinous basic nitrate from the aq. soln. C. F. Hollunder stated that the aq. soln. deposits flakes of aluminium hydroxide slowly in the cold, rapidly when heated. According to L. Liechti and W. Suida, aluminium nitrate, $Al_2(NO_3)_6$, is obtained from the normal aluminium sulphate and lead nitrate, and gives the following compounds when treated with sodium hydrocarbonate: $Al_2(NO_3)_5OH$, $Al_2(NO_3)_4(OH)_2$, $Al_2(NO_3)_3(OH)_3$, and $Al_2(NO_3)_2(OH)_4$. By continuing the addition of alkali, a gelatinous precipitate was obtained. E. Schlumberger prepared what he regarded as nitrate of the base:

$$(HO)_4Al_2{<}\genfrac{}{}{0pt}{}{O}{O}{>}Al_2{<}\genfrac{}{}{0pt}{}{O}{O}{>}Al_2(OH)_4$$

by dissolution in cold dil. nitric acid. When the soln. is evaporated to dryness, it gives a coagulum, $Al_6O_{14}H_{10}.HNO_3$. N. M. Laporte prepared **potassium aluminium nitrate,** $Al(NO_3)_3.3KNO_3.10H_2O$, by crystallization from mixed soln. of the component salts.

§ 23. The Aluminium Phosphates

Aluminium forms a number of phosphates. There is the *orthophosphate*, $AlPO_4$; the primary and secondary orthophosphates, $Al(H_2PO_4)_3$, and $Al_2(HPO_4)_3$, as well as some mixed combinations; there is also the *pyrophosphate*, $Al_4(P_2O_7)_3$, and the acid pyrophosphate, $Al_2H_6(P_2O_7)_3$; as well as the *metaphosphate*, $Al(PO_3)_3$. In addition there are a number of normal phosphates which occur native.

A. Breithaupt[1] named an apple-green mineral, which he obtained from Messbach, Voigtland, and imperfectly analyzed, *variscite*—from Variscia, an old name for Voigtland. The analyses of the variscite by T. Petersen, A. N. Chester, R. L. Packard, A. Lacroix, W. T. Schaller, and R. Helmhacker—correspond with $AlPO_4.2H_2O$, mixed, may be, with some impurities. The mineral *kallais* of A. Damour, and A. Lacroix corresponds with $AlPO_4.2\frac{1}{2}H_2O$, and is regarded as identical with the colloidal gel-form of variscite. According to the analyses of C. U. Shepard, J. H. Teall, and A. Carnot, *redondite* from the Island of Redonda, Antilles, etc., agrees roughly with variscite in composition, allowing for some of the alumina being replaced by ferric oxide. C. W. Blomstrand's analysis of *berlinite*, from Westana, Sweden, corresponds with $AlPO_4.\frac{1}{2}H_2O$. E. Boricky's analysis of *zepharovichite* from Trenic, Bohemia, corresponds with $AlPO_4.3H_2O$. F. Slavik gave 1·55 for the refractive index of zepharovichite. R. Hermann, A. Kenngott, and F. A. Genth analyzed a phosphate—named *richmondite*—associated with the gibbsite of Richmond, Mass., to which the formula $AlPO_4.4H_2O$ has been assigned. O. Grosspietsch described a white colloidal form of aluminium phosphate from Jakubeny, Bukowina.

The aluminium phosphates have probably been formed in nature by the direct action of phosphatic soln. on igneous rocks, or on limestones containing clays. The phosphates were probably leachings from beds of guano. H. Leitmeier and H. Hellwig agitated soln. of ammonium phosphate for several months with kaolin, felspar, etc., and obtained products similar to many of those found in nature. A. Gautier regards an earthy mineral which he named *minervite*, because it was obtained from Minerva grotto, Hérault, as an impure hemiheptahydrated aluminium orthophosphate, $AlPO_4.3\frac{1}{2}H_2O$. Analyses by A. Carnot, and A. Lacroix make minervite appear to be a complex alkali aluminium phosphate. A. Gautier claimed also to have found crystals of minervite in the earthy mass.

A. de Schulten obtained well-defined crystals of **aluminium orthophosphate,** $AlPO_4$, by heating in a sealed tube at 250° for several hours, a conc. soln. of sodium aluminate acidified with phosphoric acid. The presence of sodium phosphate seems to be necessary for the production of good crystals because if a mixture of phosphoric acid and aluminium hydroxide or chloride be heated under similar conditions, a fine crystalline powder is obtained. E. Erlenmeyer obtained a monohydrate $AlPO_4.H_2O$, by boiling in a flask fitted with a reflux condenser, aluminium dihydrophosphate with 20 times its weight of water for 4 hrs. and filtering the soln. hot. A. Gautier synthesized minervite by the action of a soln. of 3 mols of ammonium hydrophosphate on a mol of gelatinous aluminium hydroxide at 30°; washing the product with cold water; dissolving it in hydrochloric acid; and precipitating by the addition of sodium acetate.

According to C. F. Rammelsberg, the orthophosphate is obtained as a gelatinous precipitate by adding a soln. of sodium hydrophosphate to one of alum and washing until the runnings are free from sulphates. M. Millot precipitated aluminium phosphate from a soln. of aluminium phosphate in an acid, by the addition of aq.

ammonia. N. R. Dhar and co-workers found lime is readily adsorbed by the precipitated phosphate.

H. Ludwig said that the precipitated orthophosphate does not have the composition represented by the formula $AlPO_4$ with $Al_2O_3 : P_2O_5$ in the ratio 1 : 1. P. Schweitzer made a similar claim, although the analyses of C. F. Rammelsberg, G. C. Wittstein, and M. Millot correspond with the 1 : 1 ratio. According to F. K. Cameron and L. A. Hurst, aluminium phosphate prepared by adding a soln. of sodium phosphate to one of aluminium phosphate, and washing the product alternately with hot and cold water until free from sulphates, contained 77·42 per cent. PO_4 and 21·49 per cent. Al—theory for $AlPO_4$ is 77·80 per cent. PO_4 and 22·20 per cent. Al. A phosphate was prepared by using ammonium phosphate as precipitant, and partly neutralizing the acid-liquid with ammonium carbonate; the washed product was heated over a blast-lamp. It contained 81·33 per cent. PO_4, and 21·16 per cent. Al. Another phosphate made by precipitation with sodium phosphate from a soln. of aluminium sulphate in the presence of sodium acetate, contained 48·79 per cent. PO_4 and 19·82 per cent. Al. H. Ludwig also noted that the precipitation of aluminium phosphate from its soln. in hydrochloric acid, by the addition of sodium acetate, is highly basic. M. Millot said that the proportion of water in $AlPO_4 : H_2O = 1 : 1$; G. C. Wittstein, 1 : 4; and C. F. Rammelsberg, 1 : 4·5 if air-dried, and 1 : 3 or 4 if dried over sulphuric acid. W. J. Sell prepared **colloidal aluminium orthophosphate** sol by mixing a 5 per cent. soln. of $AlCl_3$ with an equal vol. of a 10 per cent. soln. of $(NH_4)_2HPO_4$, and adding aq. ammonia until the soln. smells feebly ammoniacal. The crystalloids are removed by dialysis. The soln. is neutral, and tasteless; and it can be flocculated by adding different salts. C. Elschner described the colloidal phosphate he found on Washington Island, South Seas, showing Liesegang's rings, and supposed to have been formed by the decomposition of lava by guano constituents. H. Leitmeier and H. Hellwig studied the formation of phosphates by the prolonged action of ammonium phosphate soln. on aluminophosphates.

According to W. T. Schaller, the crystals of variscite belong to the rhombic system and have the axial ratios $a : b : c = 0·8952 : 1 : 1·0957$. The salt prepared by A. de Schulten was in the form of hexagonal prisms of sp. gr. 2·59. The sp. gr. of crystalline variscite is 2·51, and of gel variscite 2·135; that of berlinite, 2·64; that of zepharovichite, 2·384 or 2·37 after subtracting 5 per cent. of free quartz; and that of richmondite, 2·20–2·38. The hardness of crystalline variscite is 4, that of gel variscite about 2; that of berlinite, the same as quartz; and that of zepharovichite, 5·5. The crystals do not lose weight at a bright red heat, and do not melt at a white heat. A. Gautier found a sample of minervite which lost 13·40 per cent. of water at 100°; or 23·95 per cent. at 180°; and all the water, *i.e.* 28·30 per cent., at a red heat. W. T. Schaller found that pale-green crystalline variscite lost 5·09 per cent. of water at 110° in one day, and 12·48 per cent. in 3 days; it lost 19·81 per cent. at 140°; and 22·50 per cent. at 163°. R. Helmhacker found that gel variscite over conc. sulphuric acid, lost 16·11 per cent. of water at 100°; 19·64 per cent. at 110°; 23·22 per cent. at 130°; and 26·50 per cent. at 160°. Variscite has the indices of refraction $\alpha=1·447$, $\beta=1·448$, $\gamma=1·450$; the double refraction $\gamma-\alpha=0·003$ is quite small. The mineral is pleochroic. W. T. Schaller found a green-coloured dimorphous variety of variscite which he named *lucinite*. The rhombic crystals have the axial ratios, 0·8729 : 1 : 0·9788; sp. gr., 2·566; hardness, 5; refractive indices, $\alpha=1·546$, $\beta=1·556$, $\gamma=1·578$; the birefringence, $\gamma-\alpha=0·03$, is high; and it is not pleochroic. W. W. Coblentz found that in the ultra-red transmission spectrum of variscite the water absorption bands at 1·5μ, 2μ, and 4·75μ are almost obliterated, and those at 3μ and 6μ are shifted, being probably composites. No marked evidence of a band peculiar to the PO_4-radicle was obtained. In the ultra-red reflection spectrum there are maxima at 9·25μ and 9·7μ. The latter is not well defined and corresponds with a band found in apatite, but it is not definitely proved to be peculiar to the PO_4-group.

J. N. von Fuchs said aluminium phosphate is insoluble in water, but F. K. Cameron and L. A. Hurst found that 35 days' shaking of three samples of aluminium phosphate resulted in the dissolution of respectively 0·241, 0·134, and 0·081 grm. of PO_4 per litre. This shows the slow soln. of phosphoric acid, and that while a greater proportion passes into soln. with increasing proportions of water to solid, the conc. of the soln. is less. With soln. of **potassium chloride** or **sulphate,** and **sodium nitrate,** the amount of phosphoric acid passing into soln. is less, as the proportion of alkali salt increases. According to G. T. Gerlach, the presence of **carbon dioxide** in the soln. has no effect on the solubility even in the presence of lime or magnesia. W. F. Sutherst said that the presence of **calcium hydroxide** increased the solubility of aluminium phosphate in aq. soln., but **calcium carbonate** has no effect whatever. A. de Schulten's crystals were insoluble in conc. **nitric acid** and **hydrochloric acid,** and were attacked with difficulty by conc. **sulphuric acid.** Variscite is insoluble in boiling hydrochloric acid, but if the mineral has been pre-heated, it is soluble in that acid. G. S. Fraps found that the calcined mineral is about 10 times more soluble in 0·2*N*-nitric acid than the ordinary mineral. J. N. von Fuchs, G. C. Wittstein, and H. Löwig commented on the solubility of precipitated aluminium phosphate in mineral acids and its low solubility in **acetic acid.** According to F. J. Otto, if a soln. of aluminium phosphate in hydrochloric acid be mixed with tartaric acid, and then with ammonia and magnesium chloride, the alumina remains in soln., and the phosphoric acid is all precipitated as ammonium magnesium phosphate. J. N. von Fuchs found that **lead acetate** precipitates part of the phosphoric acid as lead phosphate from a nearly neutral soln. of aluminium phosphate; and H. Rose, that **silver nitrate** precipitates silver phosphate from an ammoniacal soln. of aluminium phosphate. According to C. F. Rammelsberg, by adding potassium sulphate to the soln. of aluminium phosphate in sulphuric acid, nearly all the aluminium separates as crystals of alum. According to F. Sestini, a litre of 2 per cent. acetic acid dissolves 0·395 grm. of precipitated aluminium phosphate, and a litre of 10 per cent. acetic acid, 0·300 grm. The soln. does not become appreciably turbid when boiled. G. T. Gerlach found that **oxalic acid** and **citric acid** are about equally effective, and more so than acetic acid, in bringing phosphoric acid into soln., and that free aluminium hydroxide, while greatly reducing the action of acetic acid, does not affect oxalic and citric acids. According to E. A. Schneider, the solubility is increased by aluminium sulphate or chloride. Aluminium phosphate was found by M. Millot to be more readily dissolved than ferric phosphate by soln. of **ammonium oxalate** or **ammonium citrate.** E. Erlenmeyer has measured the solubility in citrate soln. Aluminium phosphate is decomposed by fused **sodium carbonate;** and when heated with **alkali sulphate,** L. Grandeau noted that crystalline alumina, and a complex alkali aluminium phosphate are formed According to T. Schlösing, aluminium phosphate is not decomposed when heated with **carbon,** but with **iron** and **silica,** some iron phosphide is formed.

According to H. Ludwig, aluminium phosphate gives up very little phosphoric acid to aq. **ammonia,** and a little alumina passes into soln. L. L. de Koninck and A. Thiriart state that aq. ammonia dissolves aluminium phosphate only in the presence of an excess of alkali phosphate or arsenate, and that it is precipitated from the soln. by acetic acid. C. F. Rammelsberg stated that a soln. of **potassium carbonate** abstracts only part of the phosphoric acid, but L. N. Vauquelin found that with a prolonged digestion all the phosphoric acid and some alumina pass into soln. J. N. von Fuchs found that aluminium phosphate is readily dissolved by a soln. of **potassium hydroxide,** and is precipitated unchanged from that soln. by ammonium chloride; **calcium hydroxide** or **chloride,** or **barium chloride** precipitates all the phosphoric acid in the soln. as calcium or barium phosphate, while the alumina remains in soln.; and a soln. of silicic acid precipitates a double aluminium potassium silicate leaving the phosphoric acid in soln. H. Ludwig found that hydrogen sulphide, or ammonium sulphide, precipitates an aluminium phosphate from the alkaline soln. while some phosphoric acid remains in soln. According to H. Rose, and E. Fleischer, aluminium phosphate dissolves readily in soln. of **alum, aluminium acetate,** or other **aluminium salts ;** consequently, the addition of the first few drops of sodium phosphate to an aluminium salt soln. gives no precipitation. H. Rose said that the alum soln. becomes turbid when heated, and clear again on cooling. L. Liechti and W. Suida found that a soln. containing 2 mols of **aluminium sulphate** can dissolve a mol of aluminium phosphate.

A. F. de Fourcroy dissolved aluminium phosphate in phosphoric acid and obtained a sticky mass on evaporation ; the product fused to a clear glass. M. Millot obtained what he regarded as hydrated **aluminium hydrophosphate,** $Al_2(HPO_3)_3.6\frac{1}{2}H_2O$, by boiling a clear mixture of six mols of ammonium dihydrophosphate and two mols of aluminium sulphate in the presence of sulphuric acid to prevent the precipitation of aluminium hydroxide. The salt loses 3 mols. of water at 110°, and after calcination it is insoluble in acids. E. Erlenmeyer, and P. Hautefeuille and J. Margottet obtained **aluminium hydrophosphate,** $Al(H_2PO_4)_3$, by evaporating on a water-bath a soln. of a mol of normal aluminium phosphate in 11 mols of phosphoric acid. The resulting white powder contains micro-crystalline particles. The salt is soluble in a little cold water, but when a dil. soln. (1 : 20) is boiled normal aluminium phosphate is deposited. Some products are not well defined—thus, E. Erlenmeyer reported $Al_4(H_2PO_4)_2.(HPO_4)_5$; M. Millot, $Al_2(H_2PO_4)_2(HPO_4)_2.5H_2O$; and E. Erlenmeyer, $Al_2(H_2PO_4)_4(HPO_4).2H_2O$. B. de C. Marchand obtained soft, white, or cream-coloured aluminium phosphate of the composition $Al_2O_3.2P_2O_5.8H_2O$ in a deposit of bat guano at Ermelo. It is probably a colloidal adsorption product.

According to G. C. Wittstein, and H. Rose, the addition of normal sodium pyrophosphate to a soln. of aluminium chloride or of alum, precipitates white **aluminium pyrophosphate,** which dissolves in an excess of either constituent of the parent soln., and is not re-precipitated by the addition of ammonia, or ammonium sulphide, and is not soluble in acetic acid. A. Schwarzenberg's analysis corresponds with $Al_4(P_2O_7)_3.10H_2O$, and he found that the soln. in sulphurous acid gives a precipitate on boiling. Normal aluminium pyrophosphate dissolves in aq. ammonia and alkali-lye. P. Hautefeuille and J. Margottet obtained doubly refracting needles of **aluminium hydropyrophosphate,** $Al_2H_6(P_2O_7)_3.H_2O$, by keeping a soln. of alumina in phosphoric acid, at 150°-200°, for some time.

R. Maddrell prepared **aluminium metaphosphate,** $Al(PO_3)_3$, by evaporating to dryness a soln. of alumina in phosphoric acid, and heating the residue to 316°. F. Warschauer found aluminium metaphosphate crystallizes from aq. soln. in tetrahedra. He made the salt by gradually adding aluminium hydroxide to a soln. of phosphoric acid, and evaporating the soln. on a water-bath ; P. Hautefeuille and J. Margottet, by melting alumina with four times its weight of metaphosphoric acid. The dominant form of the crystals is a combination of the cube with the octahedron, or triakisoctahedron. The faces are frequently curved. Aluminium metaphosphate crystallizes in pseudo-cubic crystals from fused metaphosphoric acid containing a small quantity of trisilver phosphate, but if the silver phosphate is present in notable proportion, birefractive crystals which act strongly on polarized light are obtained in addition to the metaphosphate. These crystals are formed exclusively by fusing 2 parts alumina with 4·6 parts metaphosphoric acid and 8 parts silver phosphate, and the same result is obtained by fusing aluminium metaphosphate with about three times its weight of silver phosphate. The double phosphate thus obtained has the composition $2Al_2O_3.Ag_2O.4P_2O_5$, and forms colourless perfectly transparent crystals derived from rhombic prisms. It is not very stable in the fused mixture, and the presence of a slight excess of metaphosphoric acid causes the formation of monoclinic crystals of aluminium pyrophosphate, Al_2O_3, $2P_2O_5$, free from silver. The presence of an excess of silver phosphate converts the original crystals of the pyrophosphate into acute octahedrons, apparently derived from a monoclinic prism, and having the composition $2Al_2O_3$, $3P_2O_6$. The salt is insoluble in water and in acids K. R. Johnson found the sp. gr. to be 2·779.

According to L. Liechti and W. Suida,[2] sodium phosphate, Na_2HPO_4, does not produce a precipitate when treated with an excess of aluminium sulphate. They found that it requires two mols of aluminium sulphate to keep one mol of aluminium phosphate in soln. By treating a soln. of alum with sodium phosphate in excess, C. E. Munroe obtained a basic aluminium phosphate, $2Al_2O_3.P_2O_5.8H_2O$, or **aluminium trihydroxyphosphate,** $AlPO_4.Al(OH)_3.2\frac{1}{2}H_2O$. G. C. Wittstein obtained a product with nearly the same composition by digesting normal aluminium phosphate with aq. ammonia for 24 hrs. J. N. von Fuchs, and M. Millot obtained $3Al_2O_3.2P_2O_5.8\text{–}12H_2O$, or **aluminium trihydroxydiphosphate,** $2AlPO_4.Al(OH)_3.nH_2O$, by the action of aq. ammonia on aluminium phosphate. C. F. Rammelsberg also obtained a basic phosphate by the action of aq. ammonia on a soln. of aluminium phosphate in hydrochloric acid. These basic salts appear to be intermediate stages in the dephosphorization of aluminium phosphate. As might have been anticipated, the basic aluminium phosphates are represented in nature. The mineral *wavellite* was for a time confused with gibbsite or hydrargillite (*q.v.*). Analyses have been made by J. J. Berzelius, H. Erdmann, R. Hermann, F. L. Sonnenschein, A. H. Church, J. N. von Fuchs, G. Städeler, F. Zambonini, F. A. Genth, F. Pisani, A. Gages, A. J. Moses and L. McL. Luquer, H. Gorceix, A. Carnot, E. F. Smith, etc. The analyses show from 1·7 to 3·6 per cent. of fluorine. C. F. Rammelsberg gives the formula $3Al_2O_3.2P_2O_5.12H_2O$; A. Carnot, $2(Al_2O_3.P_2O_5).Al_2(O_3, F_6).13H_2O$; and P. Groth, $(Al.OH)_3(PO_4)_2.5H_2O$, or pentahydrated aluminium trihydroxyphosphate. The crystals are rhombic bipyramids, with $a:b.c$ -0·5573 : 1 : 0·4084, according to G. Cesaro; or 0·55725 : 1 : 0·40572, according to H. Ungemach. The sp. gr. often determined along with the above-named analyses range from 2·33 to 2·492; F. Slavik gave 2·410, and hardness 3 to 4. The m.p. is high—F. Zambonini, F. Slavik, C. F. Plattner, and R. Cusack did not succeed in melting it; but G. Spezia fused it on its edges. F. Slavik gave 1·545 for the refractive index. A. des Cloizeaux, A. Lacroix, and G. Cesaro measured the optical constants; the double refraction is positive $\gamma-\alpha=0·0245$. W. W. Coblentz found the ultra-red transmission spectrum showed water-bands at $1·5\mu$ and 2μ; but the mineral was opaque at 3μ. The mineral is soluble in acids, and in alkali-lye; and G. S. Fraps found the solubility is increased if the mineral has been calcined. B. Kosmann, and F. Cornu and A. Himmelbauer described a *lime-wavellite* which is possibly a mixture of calcium and aluminium phosphates.

The so-called *pseudo-wavellite* of F. Henrich contains 13 per cent. CaO; about one per cent. of BaO and SiO; and 2–3 per cent. of rare earths. The amorphous mineral *vashegyite* from Vashegy (Hungary), analyzed by K. Zimanyl, is represented by the formula $4Al_2O_3.3P_2O_5.30H_2O$. Its sp. gr. is 1·964; its hardness 2. The earthy mineral *trolleite* was analyzed by C. W. Blomstrand, and represented by the formula $4Al_2O_3.3P_2O_5.3H_2O$. Its sp. gr. is 3·10, and its hardness 5·5 R Hermann's *planerite* found in the Urals, has a composition corresponding with a mixture $4(Al_6P_4O_9.9H_2O)$, $3\{(Cu, Fe)O.H_2O\}$. The cryptocrystalline mineral *cœruleolactite* has a composition corresponding with $3Al_2O_3.2P_2O_5.10H_2O$, according to the analyses of T. Peterson, and F. A. Genth. The sp. gr. is 2·57–2·696, and the hardness 5. H. Leitmeir considers cœruleolactite to be a variety of planerite. C. W. Blomstrand, and G. T. Prior and L. J. Spencer analyzed the mineral *augelite*, and the latter represented it by the formula $2Al_2O_3.P_2O_5.3H_2O$, or $AlPO_4.Al(OH)_3$. The monoclinic crystals have the axial ratios $a:b:c=1·6419:1:1·2708$ and $\beta=67°\ 33·5'$; the sp. gr. is 2·696 at 22°; the hardness is 4 to 5; and the indices of refraction $\alpha=1·5736$, $\beta=1·5759$, and $\gamma=1·5877$. Water begins to be evolved at 360°. The mineral is slowly dissolved by hot conc. hydrochloric acid. The mineral *peganite*, according to the analyses of R. Hermann, and A. Breithaupt, has the composition $2Al_2O_3.P_2O_5.6H_2O$; the crystals are rhombic bipyramids; the sp. gr. is 2·46; the hardness 3·0–3·5. L. F. Navarro and P. Castro-Barca reported a cryptocrystalline, feebly birefringent mineral occurring in yellowish-green crusts on the granite at Pontevedra, Spain. They called it *bolivarite*. Its sp. gr. is 2·05; hardness 2; and composition $AlPO_3.Al(OH)_3.H_2O$. It thus resembles peganite very closely. R. Hermann's analysis of *fischerite* corresponds with

$2Al_2O_5.P_2O_5.8H_2O$; the crystals are rhombic bipyramids which N. von Kokscharoff found to have the axial ratios $a:b:c=0·5917:1:—$. According to F. Cornu, and J. Krenner, the mineral also occurs in a colloidal state. E. S. Larsen showed that a colloidal form of fischerite agreed with planerite, and a fibrous form with vashegyite; while E. T. Wherry made the Ural fischerite agreed with wavellite. F. Slavik gave 1·533 for the refractive index of the colloid. The sp. gr. is 2·46; the hardness 5; and the double refraction positive. V. von Zepharovich, and F. Kovai analyzed the mineral *sphärite* from St. Benigna (Bohemia) with a composition corresponding with $5Al_2O_3.2P_2O_5.16H_2O$. F. Slavik gave 1·563–1·575 for the refractive index; its sp. gr. is 2·53–2·617. The analyses of the amorphous mineral *evansite* by D. Forbes, F. Becke, F. Kretschmer, H. G. Smith, F. Kovai, and W. T. Schaller correspond with the formula $3Al_2O_3.P_2O_5.18H_2O$, or $AlPO_4.2Al(OH)_3.6H_2O$. The sp. gr. ranges from 1·842 to 1·939; the hardness is about 3; the index of refraction 1·485. W. T. Schaller found the loss of water when progressively heated to different temp. to be 107°, 20·00 per cent.; 175°, 7·36 per cent.; 255°, 3·13 per cent.; 290°, 0·94 per cent.; dark redness, 3·90 per cent.; and before the blowpipe flame, 1·61 per cent. R. Hermann reported an aluminium phosphate from the mines at Gumeshevsk, Ural, with Al_2O_3, 37·48 per cent.; P_2O_5, 33·94; and H_2O, 20·93 with a number of accessory constituents. He called it *planerite*—after M. Planer. The sp. gr. was 2·65; hardness, 5; and birefringence, $\gamma-\alpha=0·0173$. H. Leitmeier has described a crystalline and amorphous aluminium phosphate, $Al_6P_4O_{19}.18H_2O$, or planerite, from Jakubeny near Bukovina. It lost $10H_2O$ at 100°. Its index of refraction was 1·5167; and it adsorbed copper oxide from an ammoniacal soln. of cupric sulphate. O. Grosspistsch gave 1·998 for the sp. gr., and said that H. Leitmeier had got wrong with the analysis, and that the mineral is not planerite, but a mixture of $Al(OH)_4PO_2.H_2O$, and $Al_2F(OH)PO_3.H_2O$.

L. J. Cohen[3] prepared **ammonium aluminium dihydrophosphate,** $(NH_4)H_2PO_4.AlPO_4$, by adding a large excess of ammonium hydrophosphate, $(NH_4)_2HPO_4$, to a strongly acid soln. of aluminium chloride. The salt is partially hydrolyzed when repeatedly washed with water. J. J. Berzelius precipitated **lithium aluminium phosphate** by adding a lithium salt to a sat. soln. of aluminium phosphate in potash-lye. C. F. Rammelsberg represented its composition $2Li_3PO_4.AlPO_4.15H_2O$. Lithium aluminium phosphate is represented in nature by the mineral *amblygonite*—ἀμβλύς, blunt; γόνυ, angle. L. Moissenet's *montebrasite* from Montebras, and *hebronite* from Hebron (Maine) were identified with amblygonite by C. F. Rammelsberg. Analyses were made by H. Backlund, J. J. Berzelius, C. F. Rammelsberg, L. Moissenet, F. von Kobell, F. Pisani, S. L. Penfield, W. T. Schaller, H. Lasne, etc. The best representative formula was discussed by S. L. Penfield, C. F. Rammelsberg, and H. Lasne; that most generally accepted is $LiPO_4:Al(OH,F)_3$, wherein a part of the lithium may be replaced by sodium or potassium The mineral usually occurs in earthy masses, the crystals, according to J. D. Dana, belong to the triclinic system, and have axial ratios $a:b:c=0·73337:1:0·76332$, and $\alpha=108°\ 51\frac{1}{4}'$; $\beta=97°\ 48\frac{1}{8}'$; and $\gamma=106°\ 26\frac{2}{3}'$. The sp. gr. is 3·03 to 3·07; and the hardness 6. A. Lacroix and A. Michel-Lévy, and A. des Cloizeaux examined the optical properties of the crystals—the double refraction is negative; the indices of refraction for Na-light are $\alpha=1·579$; $\beta=1·593$; and $\gamma=1·597$. The mineral fuses readily before the blowpipe flame. It is readily dissolved by sulphuric acid, but less readily by hydrochloric acid.

An earthy variety called *natronamblygonite*, analyzed by W. T. Schaller, corresponds with $NaPO_4.Al(OH,F)$ in which some sodium is replaced by lithium. Its sp. gr. is 3·01–3·06; and its hardness 5·5. It readily fuses; and it dissolves with difficulty in sulphuric acid. The mineral *morinite* analyzed by A. Carnot and A. Lacroix has a composition $3AlPO_4.Na_2HPO_4.3CaF_2.8H_2O$, or $Na_2H(PO_4)_3(AlF)_3.(CaF)_3PO_4.8H_2O$. The crystals are monoclinic; the sp. gr. 2·94; and the hardness $4\frac{1}{2}$. A. Lacroix' *soumansite* closely resembles morinite. The *wardite* of J. M. Davidson is considered to be either $Al_2(OH)_3PO_4.\frac{1}{2}H_2O$, or $NaAlPO_4.Al(OH)_3.\frac{1}{2}H_2O$.

L. Ouvrard obtained thin mica-like plates of **sodium aluminium phosphate,** $Na_3PO_4.2AlPO_4$, by cooling a sat. soln. of alumina in molten sodium pyrophosphate, and extracting the cold mass with water. The sp. gr. is 2·1 at 20°; the salt is soluble in nitric acid. C. N. Pahl obtained microscopic prisms of the composition $4Na_2O.2Al_2O_3.5P_2O_5.30H_2O$, or $2Na_4P_2O_7.Al_4(P_2O_7)_3.30H_2O$, **sodium aluminium pyrophosphate,** by crystallization from a soln. of aluminium pyrophosphate in one of sodium pyrophosphate. J. F. Persoz also obtained what he regarded as a double pyrophosphate by adding sodium pyrophosphate to a soln. of an aluminium salt. K. Wallroth, and L. Ouvrard obtained $Na_2O.Al_2O_3.2P_2O_5$, or $NaPO_3.AlPO_4$, from a soln. of alumina in molten microcosmic salt. The sp. gr. is 2·7 at 20°. In L. Grandeau's synthesis of corundum by fusing a mixture of aluminium phosphate and potassium sulphate, he obtained an indefinite potassium aluminium phosphate. L. Ouvrard dissolved alumina or aluminium phosphate in molten sodium ortho- or pyro-phosphate—preferably with some potassium chloride as well—and, on slow cooling and extraction with water, obtained lamellar crystals of potassium aluminium phosphate, $3K_2O.Al_2O_3.3P_2O_5$. The crystals are probably monoclinic, and the sp. gr. 2·3 at 20°. He also obtained monoclinic prisms of potassium aluminium pyrophosphate, $K_2O.Al_2O_3.2P_2O_5$, by slowly cooling a soln. of alumina in molten potassium metaphosphate, and extracting the mass with water. The sp. gr. is 2·8 at 20°; the crystals are insoluble in acids.

The **copper aluminium phosphates** are represented in nature by *henwoodite*, and *turquoise*. The former, found by J. H. Collins[4] in Cornwall, has the composition $CuO.2Al_2O_3.P_2O_5.10H_2O$; sp. gr. 2·67; and hardness, 4–4·5. The turquoise has been used as an ornament from remote antiquity; and excavations in Egypt show that it was employed in that country prior to the first dynasty—over 5500 B.C., according to W. M. F. Petrie—a time into which history does not penetrate. The name **turquoise** is French in form and means Turkish, since the gem came into Europe *viâ* Turkey. Theophrastus in his Περὶ λίθων (c. 315 B.C.) mentions a copper-stained fossil ivory, which no doubt refers to what is now known as *bone turquoise*, or *odontolite*—ὀδούς, tooth. Pliny in his *Historia naturalis* (c. 77 A.D.) refers to the *callais* which is generally regarded as greenish-blue turquoise, also to *callaina*, which may have been a greenish turquoise, and to *callaica*, which is regarded as nothing but *callaina*. There is, however, some doubt about the modern equivalents of Pliny's terms. There are numerous references to the turquoise by subsequent writers *e.g.* J. D. Mylius, G. Agricola, A. B. de Boot, T. Nicols, etc. Up to the beginning of the nineteenth century, odontolite was confused with the turquoise. The early analyses by J. F. John, B. Lagrange, and G. de W. Fischer showed that the two are essentially different. Analyses by R. Hermann, A. H. Church, A. Carnot, A. Frenzel, P. Zellner, P. D. Nikolajeff, S. L. Penfield, F. W. Clarke, T. Petersen, G. T. Moore, W. T. Schaller, J. M. Curran, F. A. Genth, W. P. Blake, etc., range from:

CuO	Al_2O_3	Fe_2O_3	P_2O_5	H_2O
2·02–9·00	31·6–50·75	0·21–7·8	13·93–34·89	11·86–21·0 per cent.

with FeO, 0·91–5·32; CaO, 0·13–7·93; MgO, 0–0·15; MnO, 0–0·68; SiO_2, 0–12·57 per cent. The analyses show a fairly wide range in composition due partly to faulty methods, and partly to the variations which are common to minerals in an amorphous state. There has been some discussion as to the constitution of the mineral. F. W. Clarke regards the mineral as a variable mixture of the two salts $2Al_2O_3.P_2O_5.5H_2O$ and $2CuO.P_2O_5.4H_2O$—or the formula becomes $Al_2HPO_4(OH)_4$, coloured with the cupric phosphate. P. Groth writes the formula of an idealized turquoise, $PO_4Al_2(OH)_3.H_2O$, or $PO_4H\{Al(OH)_2\}_2$ in which part of the Al_2 may be replaced by Cu_3, Fe_3, or Ca_3. A. Carnot gave $(Al_2, Cu_3, Fe_3)O_3.P_2O_5.Al_2O_3.5H_2O$. S. L. Penfield believed that the iron and copper are essential constituents of turquoise, and not impurities; and since the water is not expelled at a low temp., he assumed that the hydrogen is present as hydroxyl-groups and not as water of crystallization. He said that turquoise can be regarded as a derivative of orthophosphoric acid, H_3PO_4, in which the hydrogen atoms are replaced by the univalent radicles $\{Al(OH)_2\}'$, $\{Fe(OH)_2\}'$, and $\{Cu(OH)\}'$ in no fixed ratios, although the $Al(OH)_2'$ radicle always predominates. This gives $\{Al(OH)_2, Fe(OH)_2, Cu(OH), H\}_3PO_4$ for the formula of idealized turquoise. W. T. Schaller derives the formula of triclinic turquoise from $CuO.3Al_2O_3.2P_2O_5.9H_2O$, isomorphous with chalcosiderite, $CuO.3Fe_2O_3.2P_2O_3.9H_2O$; and in conformity with S. L. Penfield's arguments, he writes the formula $CuOH.\{Al(OH)_2\}_6H_5(PO_4)_4$. His analyses show that the radicles

$Al(OH)_2$, $Cu(OH)$, and H are present in the proportions 6 : 1 : 5. According to M. Bauer, and N. Heaton, imitations of the turquoise are made by subjecting to hydraulic press. for a long period, freshly precipitated and moist mixtures of precipitated aluminium phosphate and copper phosphate. The synthetic turquoise is very difficult to distinguish from the mineral.

The colour of turquoise ranges from a fine sky-blue to an unsightly green; the most approved tint for the gem-stone is the so-called sky-blue or robin's egg blue. Comparatively few stones are free from the green tinge and the value usually lessens as the green tinge predominates. In some cases, there are inclusions of foreign matter—limonite, quartz, vein matter, etc.—and if an appreciable amount is present, the material is called *turquoise matrix*. The colour of turquoise is due to copper, tinted more or less with iron. H. Bücking said the colour is due to copper phosphates; G. T. Moore, to a copper aluminate; and F. W. Clarke, to a hydrated copper phosphate. S. L. Penfield, and W. T. Schaller have shown that the colour is more probably due to the presence of copper as an integral part of the molecule. The colours of some samples of turquoise fade soon after the mineral has been mined; other samples retain a good colour for an indefinitely long period. The cause of the alteration in colour is not known, although it has been attributed to a spontaneous dehydration of the molecule. W. T. Schaller noticed that crystallized turquoise retained its colour up to 200°; while H. Bücking noted a change in colour at the temp. of molten Canada balsam as used in the preparation of microscopic slides. Turquoise occurs massive; a crystalline specimen was identified in 1911. W. T. Schaller found that the crystals belong to the triclinic system with axial ratios $a : b : c = 0{\cdot}7910 : 1 : 0{\cdot}6051$, and $\alpha = 92° 58'$; $\beta = 93° 30'$; and $\gamma = 107° 41'$. The crystals are transparent and pleochroic. Microscopic studies have been made by G. de W. Fischer, H. Bücking, W. T. Schaller, B. Silliman, G. T. Moore and V. von Zepharovich, F. W. Clarke and J. S. Diller, S. L. Penfield, D. W. Johnson, etc. In general, a thin slice of the mineral under the microscope appears as a confused mass of irregular grains with a high index of refraction. In some cases, there is a fibrous texture. The sp. gr. of turquoise usually ranges from 2·60–2·88, although A. Frenzel found a sample having a sp. gr. 2·39; and W. P. Blake, one of 2·426. Turquoise is soft in comparison with other gem-stones; its hardness varies a little, usually about 6, the same as felspar. It is rather brittle. H. Bücking found that when blue turquoise is heated, it first becomes green and blackens, and finally assumes a dark brown colour. Unlike glassy imitations, which fused quietly when heated in a crucible or with the tip of a blowpipe flame, natural turquoise decrepitates or crumbles with a crackling sound when heated. W. T. Schaller found that blue crystalline turquoise can be heated to 200° without changing its colour, but between 200° and 400° most of the water is given off; all the water is lost at 600°, and the colour is then green; at higher temp.. the colour is brown. G. T. Moore and V. von Zepharovich found the loss of water at different temp. to be:

	180°	*c.* 530°	*c.* 570°	*c.* 740°	*c.* 830°	*c.* 1200°
Loss H_2O . .	2·57	16·72	0·10	0·13	0·22	0·35 per cent.
Colour . .		Browning begins				Chocolate brown

The total loss of water was 20·09 per cent. R. Cusack gave 1500° for the m.p. W. T. Schaller found the indices of refraction of the crystals to be $\alpha = 1{\cdot}61$, $\gamma = 1{\cdot}65$; the double refraction is strong. Massive turquoise is also doubly refracting. A. Lacroix gave for the mean index of refraction 1·63. W. W. Coblentz found the mineral not sufficiently transparent to the ultra-red rays to show unequivocally the water-band at 3μ. There are small maxima in the ultra-red transmission spectrum at 3·3μ, 5·1μ, 5·3μ, 5·6μ, 6·3μ, and 7·6μ. No bands belonging to the PO_4-radicle could be identified. A. Buguet and A. Gascard, and C. Doelter found that turquoise is slightly transparent to X-rays. According to S. L. Penfield, powdered turquoise is only partially dissolved when heated in a sealed tube with hydrochloric acid, and the residue retains its blue colour; he hence infers that the colouring agent is chemically combined as an integral part of the mineral. M. Bauer said that the action of nitric acid on turquoise varies. In some cases, the mineral dissolves, but in other cases, the colouring matter is destroyed. W. T. Schaller found crystalline turquoise is not soluble in boiling hydrochloric acid, but it is soluble if the mineral has been heated until it is brown. P. Hautefeuille and J. Margottet melted a mixture of alumina, metaphosphoric acid, and silver phosphate, and obtained colourless, doubly refracting, rhombic, prismatic crystals of **silver aluminium phosphate,** $2Al_2O_3.Ag_2O.4P_2O_5$.

The **calcium aluminium phosphates** are represented by a number of minerals. Thus, according to the analysis of A. H. Church,[5] *tavistockite*, from Tavistock (Devonshire), has a composition approaching $Ca_3(PO_4)_2.2Al(OH)_3$, or $3CaO.Al_2O_3.P_2O_5.3H_2O$.

The *amphithalite* of L. J. Ingelstrom is less calcareous; the *cirrolite* of C. W. Blomstrand approximates $5CaO.3P_2O_5.2Al_2O_3.3H_2O$. There are a number of minerals with mixed bases in place of lime. For instance, the *jezekite* of F. Slavik occurs in monoclinic crystals with axial ratios $a : b : c = 0{\cdot}8959 : 1 : 1{\cdot}0241$, and $\beta = 105° 31{\cdot}5'$. Its composition approximates $Al_2O_3.CaO.P_2O_5.2(Na,Li)F.2(Na,Li)OH$; its sp. gr. is 2·940; its hardness 4½; its indices of refraction $\alpha = 1{\cdot}55$, $\beta = 1{\cdot}56$, $\gamma = 1{\cdot}59$. F. Slavik's mineral, *lacroixite*, has a composition corresponding with $8(Ca,Mn)O.3Al_2O_3.3P_2O_5.8Na(F,OH).4H_2O$, and occurs in monoclinic crystals with $a : b : c = 0{\cdot}82 : 1 : 1{\cdot}60$; the sp. gr. is 3·126; the hardness, 4·5; and the mean index of refraction 1·57. C. W. Blomstrand's *attakolite* has the composition $6(Ca, Mn)O.4P_2O_5.5Al_2O_3.6H_2O$. The sp. gr. is 3·09; and the hardness 5. F. Slavik's *roscherite* has the composition $3CaO.2FeO.3MnO.2Al_2O_3.4P_2O_5.10H_2O$, or $R''_2Al(OH)(PO_4)_2.2H_2O$. It forms monoclinic crystals with $a : b : c = 0{\cdot}94 : 1 : 0{\cdot}88$, and $\beta = 99° 50'$; sp. gr., 2·916; hardness, 4·5; and high negative double refraction. In the *eosphorite* of G. J. Brush and E. S. Dana, the composition approximates $2RO.P_2O_5.Al_2O_3.4H_2O$, where R denotes Mn and Fe, with a little Ca and Na. The crystals are rhombic bipyramids with $a : b : c = 0{\cdot}7768 : 1 : 0{\cdot}51502$; its sp. gr. is 3·3; and the hardness 5. The composition of the mineral *childrenite*, analyzed by C. F. Rammelsberg, and A. H. Church, approximates $2R''O.Al_2O_3.P_2O_5.4H_2O$, analogous, according to S. L. Penfield, with eosphorite, only the manganous oxide in childrenite is nearly one-third that in eosphorite. The rhombic crystals, according to W. H. Miller, have the axial ratios $a : b : c = 0{\cdot}77801 : 1 : 0{\cdot}52575$; the sp. gr. is 3·22–3·247; and the hardness 4·5–5. J. Drugman examined these two minerals. According to the analyses of L. J. Ingelström, and C. W. Blomstrand, the mineral *tetragophosphite* has a composition corresponding with $3(Fe,Mn,Mg,Ca)O.3Al_2O_3.2P_2O_5.3H_2O$; and, according to the former, *gersbyite* has the composition $3RO.9Al_2O_3.4P_2O_5.17H_2O$, where R denotes Fe, Mg, Ca, and Mn. In 1854, L. J. Ingelstrom reported rhombohedral crystals of a mineral *svanbergite*, whose analysis corresponded with $3CaO.3Al_2O_3.2SO_3.P_2O_5.6H_2O$, **calcium aluminium sulphatophosphate.** Its sp. gr. was 3·29; and hardness 6. The mineral *lazulite* with the higher proportions of calcium—say 3 per cent. CaO—has been called *calcium-lazulite*. T. L. Watson found a specimen corresponding with $(Fe,Mg,Ca)O.Al_2O_3.P_2O_5.H_2O$ on Graves Mountain, Georgia.

The mineral *hamlinite*, or *bowmanite*, is the natural representative of **strontium aluminium pyrophosphate,** and the analyses of S. L. Penfield,[6] and H. L. Bowman correspond with $\{Al(OH)_2\}_3(SrOH)P_2O_7$, or $2SrO.3Al_2O_3.2P_2O_5.7H_2O$, where Sr represents strontium with about one-seventh barium. It has been described by R. H. Solly, E. Hussak, and B. Jezek. According to the latter, the crystals are ditrigonal with $a : c = 1 : 1{\cdot}18504$, sp. gr. 3·159–3·283; hardness, 4·5; indices of refraction, $\epsilon = 1{\cdot}63870$, and $\omega = 1{\cdot}62945$; the double refraction is positive. The mineral *goyazite* of A. Damour was shown by W. T. Schaller, and E. Hussak to be probably the same as hamlinite. The mineral *gorceixite* of E. Hussak is a **barium aluminium phosphate,** $Ba(Ca, Sr, Ce)O.2Al_2O_3.P_2O_5.5H_2O$. It was analyzed by H. Gorceix, A. Damour, and E. Boutan. The sp. gr. is 3·036–3·123.

The mineral *lazulite* is a **magnesium aluminium phosphate.** It has also been called *false lapis lazuli, klaprothite, blue spar, mountain blue, natural smalt, blue felspar, mollite, voraulite*, etc. Analyses by C. F. Rammelsberg,[7] J. N. von Fuchs, J. L. Smith and G. J. Brush, R. Brandes, L. J. Igelström, C. W. Blomstrand, J. Gamper, and A. Lacroix correspond with $2R_3(PO_4)_2.3Al_2(PO_4)_3.2H_6Al_2O_6$, or, according to P. Groth, $(Mg, Fe, Ca)(PO_4)_2(AlOH)_2$. The crystals, according to K. Prüfer, are monoclinic prisms with the axial ratios $a : b : c = 0{\cdot}97496 : 1 : 1{\cdot}6483$, and $\beta=89° 13\frac{2}{3}'$; the sp. gr. is 2·78–3·122; the hardness, 5–6; and, according to A. Michel-Lévy and A. Lacroix, the indices of refraction are $\alpha=1·603$, $\beta=1·632$, and $\gamma=1·639$. The optical properties were investigated by A. von Lasaulx. W. W. Coblentz found a large water-band at 3μ in the ultra-red transmission spectrum of lazulite. There is also a band at 1·3μ. The amorphous mineral *kehoeite* from Kehoeit (Lawrence Co.) is a **zinc aluminium phosphate,** which, according to the analysis of W. P. Headden, has the composition $2(Al_2P_2O_5.9H_2O).2Al_2(OH)_6.Zn_3P_2O_8.3H_2O$

CHAPTER XXXIV

GALLIUM

§ 1. History of Gallium

Gallium was discovered by Lecoq de Boisbaudran.[1] The discovery was due to *une conception théorique* based on his views on the spectra of the elements. He observed that the spectral lines of the incandescent vapours of the different members of a family of metals are repeated with the same *disposition générale*, exhibiting regular variations. He found that with the aluminium family there was a missing term between indium and aluminium to which belonged *un corps hypothétique* with properties intermediate between those of the elements just mentioned. Aided by the spectroscope, he sought for this substance under unfavourable conditions in 1863, and in the autumn of 1868 he collected some zinc blende at Pierrefitte (Haute Pyrenees) with the object of renewing the quest. Work was recommenced in 1874, and the existence of *un nouvel élément* established during the night of August 27–28, 1875. It was named *gallium en l'honneur de la France*—Gallia being the Latin name for France. The discovery was communicated in *un paquet cacheté* to l'Academie des Sciences on August 29, 1875, and the packet was opened on September 20, 1875. P. E. Browning has compiled a bibliography of the literature of this element.

L. de Boisbaudran said that from the position attributed to *l'élément inconnu* in the chemical family he was able to predict approximately its properties, but he did not think it proper to publish these speculations, *nées de l'imagination*, without making serious efforts to control them by *résultats positifs*. Meanwhile, D. I. Mendeléeff was studying the periodic law, and in order to justify his argument that certain blanks in the periodic table were due to unknown elements, he stated that the lacuna below aluminium must belong to an undiscovered element which he named *eka-aluminium*. Bolder than L. de Boisbaudran, D. I. Mendeléeff (1869) attributed certain properties to eka-aluminium, and in 1875, he showed that gallium was vested with those very qualities—*vide*, **1**. 6, 4. A comparison of the prediction and of the observed results is made in Table I. M. M. P. Muir, and C. Winkler have discussed this subject.

TABLE I.—COMPARISON OF THE PROPERTIES OF EKA-ALUMINIUM AND GALLIUM.

D. I. Mendeléeff's Eka-aluminium, El	L. de Boisbaudran's Gallium, Ga
1. At. wt. about 68.	1. At. wt. 69·9.
2. *Metal* of sp. gr. 5·9; m.p. low; non-volatile; unaffected by air; should decompose steam at a red heat; and dissolve slowly in acids and alkalies.	2. *Metal* of sp. gr. 5·94; m.p. 30·15°; non-volatile at moderate temp.; not changed in air; action of steam unknown; and dissolves slowly in acids and alkalies.
3. *Oxide*—formula El_2O_3; sp. gr. 5·5; should dissolve in acids to form salts of the type ElX_3. The hydroxide should dissolve in acids and alkalies.	3. *Oxide*—Ga_2O_3; sp. gr. unknown; dissolves in acids, forming salts of the type GaX_3. The hydroxide dissolves in acids and alkalies.
4. *Salts* should have a tendency to form basic salts; the sulphate should form alums; the sulphide should be precipitated by H_2S or $(NH_4)_2S$. The anhydrous chloride should be more volatile than zinc chloride.	4. The *salts* readily hydrolyze and form basic salts; alums are known; the sulphide is precipitated by H_2S and by $(NH_4)_2S$ under special conditions. The anhydrous chloride is more volatile than zinc chloride.
5. The element will probably be discovered by spectrum analysis.	5. Was discovered by the aid of the spectroscope.

In 1887, E. Linnemann [2] announced a new element in the *orthite* from Arendal; he named it *austrium*. This element is considered by L. de Boisbaudran, and R. Pribram to be impure gallium, because it exhibits the two characteristic lines of that element—the differences in the number and intensity of the observed spectral lines are caused by variations in the working conditions. R. Pribram, however, said that orthite shows spectroscopically a new element yet to be isolated; he called it *austrium* and said that it is quite different from E. Linnemann's austrium. This has not been confirmed.

§ 2. The Occurrence of Gallium

Gallium is one of the scarcest of elements, but, according to W. Vernadsky,[1] W. N. Hartley and H. Ramage, it occurs widely distributed in nature in minute quantities. J. H. L. Vogt, and F. W. Clarke and H. S. Washington estimated the 10-mile crust, the hydrosphere and lithosphere contained 0·00000000*x* per cent. of gallium. Very small amounts of gallium occur in many zinc blendes. L. de Boisbaudran found it in the brown blende of Pierrefitte, Sweden, and Schwarzenberg (Saxony); in the yellow blende of Mandesse, and Asturien; in the black blende of Bensberg; in the blende of Alston Moor (Cumberland), and Rio Tuerto (Spain). The Pierrefitte blende contained 0·0014–0·0022 grm. of gallium per kgrm.; the Bensberg blende is somewhat richer, containing 0·016 grm. per kgrm. H. B. Cornwall, F. L. Bartlett, and W. F. Hillebrand and J. A. Scherrer, found it in a number of American zinc blendes; C. Rimatori, in Sardinia zinc blendes; and J. B. Kirkland, in Australian blendes from Peelwood (N.S.W.). G. Urbain, A. del Campo y Cerdan, H. C. Fogg and C. James, and W. N. Hartley and H. Ramage have discussed the occurrence of gallium in zinc blendes. The last-named found gallium in twelve out of fourteen zinc blendes which they examined; the first-named detected gallium in nearly all the 64 samples which he examined; and A. del Campo y Cerdan, in 60 of the 65 specimens investigated. Gallium, indium, and germanium were found in 29 cases; gallium and germanium in 18; gallium and indium in 4; and germanium and indium without gallium in none. Four samples showed gallium alone. L. de Boisbaudran found a little gallium in the tutia from the zinc furnaces of the Société de la Vieille-Montagne. B. Delachanal and A. Mermet found gallium in the residue remaining after the distillation of zinc—approximately 0·002 grm. of gallium in 10 kgrms. of zinc, or 1 : 5000000. P. E. Browning and H. S. Uhler found mercury-like globules of an alloy of gallium with about 10 per cent. of indium, some lead and zinc, on the surface of a residue obtained in the distillation of zinc. L. de Boisbaudran observed no gallium in the ribbon blende from Vieille Montagne, zinc from Vieille Montagne, tutia from Corphalie, galena from Pierrefitte, calamine from Sardinia and Le Gard, and in commercial hydrochloric and nitric acids. W. N. Hartley and H. Ramage demonstrated the presence of gallium, spectroscopically, in 35 out of 91 iron ores they examined—siderite, pyrites, etc.; it was found in seven magnetites; in metallic iron; in the flue dust of blast furnaces; in fifteen aluminium ores; usually in china clay and bauxite; in commercial alum; and in four out of twelve manganese ores. C. Boulanger and J. Bardet, and R. L. y Gamboa also found gallium to be present in commercial aluminium—in one case 0·017 per cent. of gallium—and in many bauxites; J. Lunt, O. Pufahl, and J. S. Thomas and W. Pugh found about half per cent. of gallium in germanite.

W. N. Hartley and H. Ramage found gallium to be present in meteoric iron, and the spectroscope showed it to be present in the sun; the latter observation was confirmed by J. N. Lockyer. W. N. Hartley has also discussed the occurrence of gallium in the sun and stars. The presence of gallium was found by J. Bardet in some French mineral waters.

§ 3. The Extraction of Gallium

L. de Boisbaudran [1] employed the following process for extracting gallium from its ores:

> The ore, according to its nature, is dissolved in aqua regia, hydrochloric or sulphuric acid. The cold liquid is treated with plates of zinc, which precipitate copper, arsenic, lead, cadmium, indium, thallium, mercury, silver, bismuth, tin, gold, and selenium: the soln. is filtered, when the escape of hydrogen is still considerable. The liquid is then heated with a large excess of zinc. The gelatinous deposit is washed, and redissolved in hydrochloric acid. The new liquid is heated with an excess of zinc, and a second gelatinous precipitate is obtained. Into the hydrochloric soln. of this second precipitate formed by zinc a current of hydrogen sulphide is passed, the liquid is filtered, the excess of hydrogen sulphide driven off, and the soln. is fractionated with sodium carbonate, ceasing when the ray Gaα 417·0 ceases to be visible with the hydrochloric soln. of the precipitate. The oxides or sub-salts are taken up with sulphuric acid; the soln. is carefully evaporated until white sulphuric acid vapours are no longer, or but slightly, given off. It is allowed to cool, and stirred with water, which dissolves the mass after the lapse of a time varying from some hours to a couple of days. The soln. of the sulphate, almost neutral, is diluted with much water, and raised to the boiling-point. The sub-salt of gallium is separated by filtration whilst hot. This basic salt is dissolved in a little sulphuric acid, and the liquid is mixed with a slight excess of potassium hydroxide, so as to dissolve the gallium, but to leave the iron. It is filtered, and the oxide of gallium is precipitated by a prolonged current of carbon dioxide. This oxide is redissolved in a minimum of sulphuric acid, a slight excess of ammonium acetate, feebly acid, is added, and it is then treated with hydrogen sulphide. Under these conditions the gallium is not precipitated. The acid liquid is filtered, diluted with water, and raised to a boil. The bulk of the gallium is precipitated and filtered whilst hot. The mother-liquor, concentrated, and boiled with aqua regia in order to destroy ammoniacal salts, is added to the other gallium residues. The precipitate formed on heating the acetic acid soln. is redissolved in sulphuric acid, a slight excess of potassium hydroxide is added, and it is then filtered. The soln. in alkali-lye is electrolyzed. The gallium is easily detached from platinum electrode on pressing it between the fingers under warm water. The metal is then immersed for about half an hour in nitric acid at about 60° or 70°, quite free from chlorine, and diluted with an equal volume of water. After washing, it may be regarded as pure.

The small proportion of gallium in the ores renders the preparation of the metal costly and laborious. The extraction of gallium from zinc ores was described by H. C. Fogg and C. James; and from germanite, by J. S. Thomas and C. James. L. de Boisbaudran and E. Jungfleisch used the following modification of the above process for extracting gallium from the blende of Bensberg, the richest ore available:

The pulverized mineral is roasted in a gas furnace, when the gallium remains fixed, while the greater part of the indium is volatilized. The residue is treated with a quantity of sulphuric acid sufficient to dissolve almost all the zinc, leaving, however, in the mass so much subsulphate of this mineral that the filtrate may be rendered turbid by cold water. We thus obtain commercial zinc sulphate and a residue containing the gallium. This residue is redissolved in an excess of sulphuric acid. After the reduction of the per-salt of iron by means of metallic zinc, the filtrate is precipitated fractionally with sodium carbonate, the progress of the operation being watched with the spectroscope. The precipitates are re-dissolved in sulphuric acid, and a second reduction with zinc and a fractional precipitation with sodium carbonate follow. All the gallium in the 4300 kilos. of ore was thus concentrated in about 100 kilos. of still moist material. To remove the iron the reductions with zinc and the fractional precipitations with sodium carbonate are repeated several times. The galliferous precipitate is redissolved in sulphuric acid, evaporated to the elimination of most of the excess of acid, and boiled with much water. The filtrate deposits a sediment containing titanic acid. The liquid, which is very much charged with zinc, is treated with hydrogen sulphide, mixed with ammonium acetate, and again treated with hydrogen sulphide. Zinc sulphide is thrown down along with gallium, which is thus freed from alumina. The additions of zinc sulphate, of ammonium acetate, and the currents of hydrogen sulphide, are repeated as long as the sulphide gives the rays of gallium. The sulphuric soln. of the galliferous sulphides of zinc is carefully fractioned with sodium carbonate, and guided by spectral examination the zinc is thus completely separated. The product is again dissolved in the theoretical quantity of sulphuric acid and treated with hydrogen sulphide when a little cadmium, lead, indium, zinc, etc., are deposited as sulphides; and the liquid, largely diluted with water, is raised to the boil. By filtering when hot we collect a bulky sub-salt of gallium which is immediately washed in boiling water, for on cooling it dissolves in its mother liquor. This basic salt is very readily attacked by alkali-lye, which leaves undissolved iron, indium, etc. The alkaline liquor on treatment with hydrogen sulphide gas, and then by very slight acidulation with sulphuric acid, yields a deposit principally consisting of indium sulphide. The very slightly acid liquid is next boiled with a large excess of water, when the sub-salt is again deposited. Metallic gallium is isolated by the electrolysis of the soln. of the sub-salt in alkali-lye. The metallic deposit is only obtained advantageously under certain special conditions. The intensity of the electric current should vary according to the conc. of the liquid, but the surface of the negative electrode must be small in comparison with that of the positive electrode. If the metal is deposited in the cold it often forms long rows of crystals resembling needles fixed to the electrode by one of their ends, and sometimes reaching 3 cms. in length. Above 30°, the metal flows in drops, which collect at the bottom of the electrode. The crude metal has been further purified by filtering it through dense linen, shaking it while hot with water acidulated with hydrochloric acid, and by repeated recrystallization.

W. N. Hartley and H. Ramage also separated gallium from iron. P. E. Browning and L. E. Porter separated gallium and zinc by the fractional crystallization of cæsium-gallium alum. R. L. y Gamboa separated gallium from aluminium by precipitating the former in hydrochloric acid soln. containing potassium arsenite, by means of hydrogen sulphide. The arsenic sulphide carries down all the gallium as sulphide. F. Bates purified gallium in the following manner:

Crude gallium was dissolved in aqua regia, treated with sulphuric acid, and heated until it fumes so as to remove nitric acid. After dilution, small amounts of lead sulphate were filtered off. The soln. was then diluted, treated with hydrogen sulphide, and filtered to remove the hydrogen-sulphide group of elements. The filtrate was boiled to expel hydrogen sulphide and treated with ammonium hydroxide. The precipitate was filtered off, dissolved, and reprecipitated three times to free it from zinc. The final separation from indium was based on the solubility of gallium hydroxide in a soln. of sodium hydroxide and the insolubility of indium hydroxide in that reagent. The sodium hydroxide separation was carried through three times. The deposition of gallium was finally carried out by electrolysis of the alkaline soln.

The electrolytic deposition of gallium from alkaline soln. of its salts or hydroxide has been studied by L. Schucht, L. Ehrlich, and G. Kunert. P. E. Browning and H. S. Uhler obtained the metal in the form of a gallium-tree when operating at 0°; at ordinary temp., the metal appears in liquid globules. L. M. Dennis and J. A. Bridgman showed that by the fractional electrolysis of a slightly acid soln. of the sulphates of gallium, indium, and zinc, zinc may be removed entirely, and the gallium obtained almost free from indium. T. W. Richards and S. Boyer found that the separation of gallium from indium by the process based on the difference in the solubilities of the hydroxides in alkali-lye leaves several per cent. of indium with the gallium. The electrolytic process based on the fact that gallium is less easily deposited than indium, and more easily deposited than zinc, gives good results.

§ 4. The Physical Properties of Gallium

Gallium is a greyish metal with a colour resembling that of steel ; it has a greenish-blue reflex, and when molten it appears like tin or silver. According to L. de Boisbaudran,[1] with repeatedly reflected light the colour is bluish-green. T. Carnelley studied the relation between the colour and at. wt. of the gallium family of elements. L. de Boisbaudran and E. Jungfleisch obtained **crystals** by introducing a platinum wire supporting a little solid gallium into the molten metal, undercooled 10°-15° below its m.p. ; in three to ten seconds, octahedral crystals are formed. If the crystals are not promptly withdrawn, the metal becomes heated too near its m.p., solidification is retarded, and plate-like crystals are formed. The lustrous crystals are difficult to measure because their surfaces are slightly curved. The metal crystallizes in bipyramids probably belonging to the monoclinic system, according to L. de Boisbaudran, or to the tetragonal system, according to A. des Cloizeaux. The solid metal has a crystalline texture.

The **specific gravity** of the samples first prepared by L. de Boisbaudran was 4·7 at 15°/15°, but he later found this result is too low—possibly owing to interstices filled with air or water ; he later obtained 5·935 at 24·45°/24·45° for the solid and 6·07 for the liquid at 24·7°. Like water, therefore, the solid contracts on melting. T. W. Richards and S. Boyer found that the purest sample of gallium they prepared had a sp. gr. 5·885 in the solid state and 6·081 in the liquid state ; gallium contaminated with indium had sp. gr. 5·975 and 6·166 respectively in the solid and liquid states. The presence of indium has thus little influence on the expansion which occurs when gallium freezes. E. Donath and J. Mayrhofer studied the at. vol. of gallium with respect to its position in the periodic table. Gallium is hard ; and it gives a bluish-grey streak on paper. The **malleability** is low. It can be extended under the hammer, but it soon becomes brittle, breaking in the direction of the crystalline cleavage on shock, or when suddenly bent. Thin foil was obtained by melting the metal between sheets of glass. T. W. Richards and S. Boyer found the **compressibility** of the purest gallium, *i.e.* the fractional change in vol. caused by one megabar press., between 100-500 megabars, to be $2·09 \times 10^{-6}$ per unit vol. per megabar, at 30° ; and that of gallium contaminated with some indium, $1·97 \times 10^{-6}$. The compressibility of the liquid at 30° is $3·97 \times 10^{-6}$, a value very near that of mercury, and nearly twice the value for solid gallium. This agrees with general experience that the compressibility of a substance in the solid state is less than that of the same substance in the liquid state irrespective of the volumes occupied.

L. de Boisbaudran measured the **melting point** of six samples of gallium successively deposited from the same soln. The first and last fractions had respectively the values 30·14° and 30·16°—the mean of all six samples was 30·15° ;

an earlier determination on a less pure sample gave 29·5°. M. Berthelot found the m.p. to be 30°, and W. Guertler and M. Pirani give this as the best representative value. The metal thus liquefies when held in the fingers, and it very readily remains in a state of surfusion. The fusion point was not changed by keeping the metal in boiling water for 2 hrs. to destroy any potassium which might be present. T. W. Richards and S. Boyer obtained 30·8° for the m.p. of the metal purified by the electrolytic process, and 26·9° for that purified by the hydroxide process without electrolysis. From T. W. Richards and S. Boyer's value for the sp. gr. of the liquid and solid at the m.p. W. R. Mott gave 30·1° for the m.p., and 1700° for the **boiling point.** According to W. R. Fielding, the metal is more polymerized in the liquid than in the solid state at the m.p. P. W. Bridgman computed that gallium contracts 0·00529 c.c. per gram in passing from the solid to the liquid state, and increasing press. accordingly depress the m.p. The m.p. at different press., *p*, in kgrms. per sq. cm. are:

p . . .	0	1000	2000	4000	6000	8000	10,000	12,000
m.p. . .	29·85°	27·8°	25·7°	21·4°	17·0°	12·6°	8·10°	2·55°

L. de Boisbaudran said that melted gallium adheres readily to glass, on which it forms a fine mirror whiter than that produced by mercury; but, added L. de Boisbaudran and E. Jungfleisch, after cooling and solidification, the metal can be readily detached from glass. L. de Boisbaudran found the metal to be but slightly volatile even at a red heat. F. Bates said that little is known concerning the **boiling point** of gallium, but a few experiments which have been made show that it is over 1500°. L. de Boisbaudran suggested using gallium in place of mercury as a thermometer liquid for high temp. M. Berthelot found the **specific heat** of solid gallium to be 0·079 between 12° and 23°; and that of the liquid between 12·5 and 119°, to be 0·082; the atomic heat of the solid is therefore 5·52, and that of the liquid 5·59. A. Eucken gave for the mol. ht. of liquid gallium C_p=5·6, and for the solid C_p=5·5. From the slope of the press.-m.p. curve 0·00203, and Clapèyron's equation, P. W. Bridgman computed the latent **heat of fusion** to be 18·5 cals. per gram. M. Berthelot found by seeding surfused gallium at 13°, the heat of fusion to be 19·11 cals. per gram of metal. P. W. Robertson discussed some relations between the physical constants of gallium.

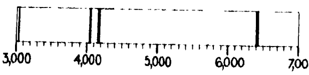

FIG. 1.—Spark Spectrum of Gallium

The **spark spectrum** of gallium was shown by L. de Boisbaudran to furnish two violet lines λ=4172·2 and 4033·18– the former is much more intense than the latter. The flame spectrum is feeble and rapidly vanishes. There are three other feebler lines for λ=6396·99 and 6413·92; and one still more feeble for λ=3020·61, Fig. 1—by F. Bates. Four of these five lines are in the visible spectrum. P. E. Browning and H. S. Uhler found indications of the possibility of two faint gallium lines λ=5353·81 and 5359·8. Lines have also been observed by B. Delachanal and A. Mermet, G. D. Liveing and J. Dewar, E. Klein, E. Demarçay, W. N. Hartley and co-workers, F. Exner and H. Haschek. While H. Kayser said that so little is really known that *alles in allem ist das Spektrum des Gallium noch so gut wie unbekannt.* The **series spectra** of the family have been studied by J. R. Rydberg, W. M. Hicks, A. Fowler, J. A. Carroll, and F. Paschen and K. Meissner. H. S. Uhler and J. W. Tanch studied the **arc spectrum** of gallium; and W. Grotrian, the **absorption spectrum.** W. Duane and K. T. Hu, and H. S. Uhler and C. D. Cooksey measured the **X-ray spectrum** of gallium, and found, in Angström units, $\alpha_2\alpha'=1\cdot34161$; $\alpha_1\alpha=1\cdot33785$; and $\beta_1\beta=1\cdot20591$. The high-frequency spectrum was also studied by M. de Broglie. F. L. Möhler and A. E. Ruark gave for the **ionization potentials,** $2p_2=5\cdot960$; $2p_1=5\cdot871$; and for the **resonance potentials,** $2p_2-2p_1=0\cdot102$; $2p_2-2s=3\cdot060$; $2p_2-3d_{1,2}=4\cdot294$. According to J. H. Gladstone, the **specific refraction,** calculated from the rubidia alum, is 0·2120; and the **atomic refraction** approximately 14·8; the sp. refraction is 0·166, and the atomic refraction 11·6 with the H_α-line. W. J. Pope gave 16·52 for the at. refraction of gallium with the *D*-line.

A. Guntz and W. Broniewsky found the specific **electrical resistance** of gallium at 0° to be 53·4 when the absolute value of a gallium filament is 1·3686, and of mercury of the same volume 2·4095 ; at higher temp. the values are :

	0°	17·4°	18·6°	26·4°	29°	30·3°	40·1°	18·6°
Sp. resistance	53·4	56·5	57·0	55·8	m.p.	27·2	28·4	28·0
	Solid					Liquid		

According to P. W. Bridgman, the sp. resistance of liquid gallium at the m.p. is $25{\cdot}92\times10^{-6}$ units ; and relative sp. resistance, *R*, of liquid gallium at different press., *p* kgrms. per sq. cm., and temp.

p		0	1000	2000	4000	6000	8000	10,000	12,000
R	30°	0·6456	0·6415	0·6380	0·6308	0·6238	0·6171	0·6105	0·6044
	65°	0·6647	0·6605	0·6564	0·6488	0·6418	0·6349	0·6283	0·6223
	100°	0·6824	0·6783	0·6743	0·6667	0·6593	0·6522	0·6451	0·6386

so that the average press. coeff. of the resistance between 0 and 12,000 kgrms. per sq. cm. is $-0{\cdot}0_5531$ at 30°, $-0{\cdot}0_5532$ at 65°, and $-0{\cdot}0_5531$ at 100°. No discontinuities were observed, showing that there is probably no new modification in the region observed. The relation between press. and resistance is linear at 0° to 12,000 kgrms. per sq. cm. press., the coeff. being $-0{\cdot}0_5217$; and in a glass capillary tube $-0{\cdot}0_5191$. The temp. coeff. of the resistance for the unconstrained solid is 0·003963 between 0° and 21·5°. The sp. resistance of solid gallium was 1·733 times that of the liquid at the m.p. ; A. Guntz and W. Broniewsky found 2·09 for this ratio. P. W. Bridgman found that for the supercooled liquid down to 0°, the resistance curve is a regular prolongation of the curve at the m.p., while A. Guntz and W. Broniewsky, and A. Schulze found the resistance, *R*, to pass through a minimum and to increase again in the unstable region:

	0°	17·4°	18·6°	26·4°	29·0°	30·3°	40·1°
$R\times10^6$	53·4	56·5	57·0	55·8	m.p.	27·2	28·4

at the m.p. the resistance of the solid is 57×10^{-6}, and of the liquid, 27×10^{-6}. J. Regnauld found that liquid gallium is electronegative to the solid metal, and he made a cell with liquid gallium acting as the positive, solid gallium as negative electrode—in a neutral aq. soln. of gallium sulphate. S. Meyer, and M. Owen found the metal to be diamagnetic.

§ 5. The Chemical Properties of Gallium

J. N. Lockyer[1] said that when gallium is heated in vacuo, no **occluded gas** is given off. According to L. de Boisbaudran and E. Jungfleisch, gallium preserves its lustre in **air**, and even in the laboratory where the air is usually loaded with acid vapours. L. de Boisbaudran said that in air at a red heat the metal is oxidized only superficially. A. Dupré found that dry **oxygen** at 285° exerts no visible action on the metal; at incipient redness, the metal loses its lustre and is covered by a very thin greyish-blue pellicle; at a full red heat, a distinct film of oxide is formed and this protects the metal from further oxidation; and at a bright red heat, a slight sublimate of oxide is formed in the hottest parts of the tube. L. de Boisbaudran and E. Jungfleisch stated that gallium remains bright in boiling **water** free from air, but, in water containing air, the metal tarnishes slowly. When crystallized gallium is thrown into hot water, it crackles, and bubbles of gas escape—possibly hydrogen occluded when the metal was electro-deposited. Gallium unites with **chlorine, bromine,** and **iodine** in the cold and in decreasing order of activity. The metal is slowly dissolved by **hydrochloric acid,** cold or hot, with the evolution of hydrogen. The action of acids is faster with the solid than with the liquid metal. The metal is slowly dissolved by **nitric acid**—faster when hot than when cold. With monohydrated nitric acid, free from nitrous vapours, the action is almost nil at ordinary temp., but at 40°–50°, the action proceeds slowly, forming a grey deposit which dissolves very slowly. **Aqua regia** is a better solvent than nitric acid, but the action is not rapid. Gallium dissolves in a soln. of **potassium hydroxide,** and hydrogen is evolved. According to F. Bates, **cadmium** readily alloys with gallium, and he used the alloy in place of cadmium alone for a cadmium vapour lamp. When solidified, the alloy does not adhere to the fused silica walls of the lamp. W. Ramsay found that gallium readily amalgamates with **mercury.** L. de Boisbaudran found that gallium readily alloys with **aluminium,** and mixtures rich in gallium are liquid at ordinary temp.; they readily decompose water, evolving hydrogen and leaving a solid residue of the metal gallium, and aluminium hydroxide. Gallium also alloys with **platinum, indium,** etc. Gallium forms two series of salts, in one the metal is a dyad, and in the other a triad. Gallous salts have reducing properties, and they are unstable. A. Korczynsky studied the catalytic effect of gallium and its salts on the hydrogenation of aromatic hydrocarbons.

Reactions of analytical interest.—The gallic salts are colourless or white; the sulphate and nitrate are readily soluble in water; the sulphate forms alums. The aq. soln. are hydrolyzed when boiled, and a basic salt is precipitated. Gallic salts give no precipitate with **hydrochloric acid.** The soln., acidified with hydrochloric, sulphuric, tartaric, or acetic acid, gives no precipitate with **hydrogen sulphide,** even if ammonium or alkali tartrates are present, but if zinc, silver, copper, manganese, iron, or arsenic are present in a feebly acid soln., some gallium is carried down with the precipitate, but not if the soln. be strongly acidified. Gallium is not precipitated by ammonium sulphide, but in presence of other salts, like those of zinc, the gallium is precipitated with the zinc sulphide. Gallic hydroxide is precipitated by soln.

of **potassium hydroxide,** or by aqua **ammonia,** and the precipitate is soluble in an excess. The presence of tartaric acid hinders the precipitation by ammonia. A white precipitate is obtained with **alkali or ammonium carbonate,** and in the latter case the precipitate is soluble in an excess of the precipitant. Gallium hydroxide is precipitated by **barium or calcium carbonate** in the cold. Similar precipitates are obtained by adding **cupric oxide** or **manganous sulphide**—in the latter case hydrogen sulphide is evolved. The precipitation with cupric oxide is utilized for separating gallium from salts of lead, cobalt, nickel, iron, thallium, beryllium, and the rare earths. When a boiling dil. soln. of a gallic salt, acidified with acetic acid, is treated with ammonium acetate, gallic hydroxide is precipitated if the precipitant is not in too great an excess. **Potassium ferrocyanide** gives a precipitate in soln. strongly acidified with hydrochloric acid. L. E. Porter and P. E. Browning based a method of analysis on this reaction which is very sensitive, a precipitate is produced in a soln. containing 1 part of gallium in 200,000 parts of soln. No precipitation occurs with **potassium ferricyanide.** The metal **zinc** gives a precipitate only with alkaline soln. of gallium salts; the gallium forms insoluble flecks of gallic oxide or of a basic salt; the reaction with **cadmium** is incomplete; and with **iron,** a long boiling is needed. In gravimetric analysis, gallium is precipitated by ammonia and weighed as sesquioxide.

The atomic weight of gallium.—The hydrogen eq. of gallium in gallous salts is about 35, and in gallic salts, 23·3. It is assumed that in the former case the metal is dyadic, and in the latter triadic, and that the at. wt. approximates 70 because this corresponds (i) with the smallest quantity of gallium in gallium trichloride when tested by the vapour density method of Avogadro; (ii) with Dulong and Petit's specific heat rule; (iii) with Mitscherlich's isomorphic law where the gallic alums are isomorphous with aluminium, indium, and thallium alums; and (iv) with the position assigned to it in the periodic table. (v) C. Runge and J. Precht's method, based on the linear relation of the logarithms of the at. wt. and the logarithm of the doublet separation of members of a family, was shown by W. M. Watts to agree with an at. wt. of about 70. L. de Boisbaudran determined the ratio ammonia gallic alum, and gallic oxide, $(NH_4)_2SO_4.Ga_2(SO_4)_3.24H_2O : Ga_2O_3$, and hence computed the at. wt. 70·08; and he also dissolved gallium in nitric acid, and ignited the nitrate so as to obtain gallic oxide, and from the ratio $2Ga : Ga_2O_3$, computed the at. wt. 69·7. In some preliminary experiments, T. W. Richards, W. M. Craig, and J. Sameshima determined the ratio $GaCl_3 : 3AgCl$, and hence computed the at. wt. 70·10; and T. W. Richards and W. M. Craig obtained 69·716. The International Table gives 69·9 for the best representative value. From the lowering of the vap. press. of soln. of gallium in mercury, W. Ramsay inferred that gallium is monatomic in the dil. soln.—this presupposes that no gallium mercurides are formed. The **atomic number** of gallium is 31. F. W. Aston found that gallium has two **isotopes** with at. masses 69 and 71.

§ 6. Gallium Oxides and Hydroxides

Gallium forms *gallium sesquioxide, gallic oxide,* or **gallium trioxide,** Ga_2O_3 ; and what may be a lower oxide, *gallous oxide* or **gallium monoxide,** GaO—but the existence of the latter is not so well established as that of the former. L. de Boisbaudran [1] obtained gallic oxide by the action of nitric acid on gallium, or by heating the nitrate. A. Dupré also found that the oxide obtained by igniting the nitrate is a white friable mass which, if heated in a stream of dry hydrogen, partly sublimes, and is partly reduced; at a cherry-red heat, said he, a bluish-grey substance is produced which resembles the pellicle formed on the oxidation of gallium; notwithstanding the blue tint, the oxide does not appear to contain appreciable traces of the metal, for on treatment with nitric acid there is no evolution of nitrous fumes. It dissolves also in dil. sulphuric acid without the evolution of any gas, and the soln. reduces potassium permanganate. It is therefore inferred that the greyish-blue matter is a lower oxide of gallium, probably gallous oxide, for the sulphuric acid soln. of gallic oxide does not reduce permanganate. L. de Boisbaudran prepared a brown oxide with similar properties to A. Dupré's gallous oxide by the action of water on gallous chloride.

Gallic oxide is infusible at a red heat. According to L. F. Nilson and O. Pettersson, the sp. ht. of the oxide is 0·1062, and the mol heat, 19·54. L. de Boisbaudran found that chromiferous gallic oxide gives a fine red fluorescence in the cathode rays. 0·1 per cent. of chromic oxide is sufficient. The oxides of samarium, dysprosium, and terbium also act as phosphorogens on gallic oxide. E. L. Nichols and H. L. Howes studied the luminescent spectrum of the incandescent oxide. Gallic oxide is soluble in hydrochloric or sulphuric acid, in an aq. soln. of alkali hydroxide, and in aq. ammonia; but if the oxide has been strongly heated, its solubility in these menstrua is so slow that L. de Boisbaudran said that it is insoluble. The calcined oxide may be brought into soln. by fusion with potassium hydrosulphate, or hydroxide. As indicated above, A. Dupré found that at a cherry-red heat, hydrogen reduces gallic oxide to a lower oxide; at a bright-red heat, the oxide is reduced to metal. C. Winkler found the oxide is reduced when heated with magnesium, forming a reguline metal.

According to L. de Boisbaudran, the precipitate obtained by treating soln. of gallium salts with alkali carbonates or hydrocarbonates; by alkali hydroxides; by aqua ammonia; and by ammonium carbonate, is probably **gallic hydroxide,** $Ga(OH)_3$. According to L. M. Dennis and J. A. Bridgman, the precipitate of hydroxide obtained by boiling a soln. of gallium sulphate with sodium trinitride, or sodium sulphite, is more curdy and more easily washed than the gelatinous precipitate obtained with aq. ammonia. The precipitated hydroxide dissolves in aq. soln. of ammonia, ammonium carbonate, or alkali hydroxide. Aq. ammonia or alkali hydroxide does not give a precipitate with soln. of gallium salts in the presence of tartaric acid, presumably, said L. de Boisbaudran, because complex gallic tartrates are formed. Gallic hydroxide is readily soluble in acids, forming soln. of the corresponding salts.

§ 7. Gallium Halides

The *fluorides of gallium* have not been investigated. According to L. de Boisbaudran,[1] gallium forms two chlorides, namely, *gallous chloride*, or **gallium dichloride,** $GaCl_2$; and *gallic chloride*, or **gallium trichloride,** $GaCl_3$. Gallous chloride is obtained by heating gallic chloride with gallium; heating an excess of gallium in chlorine; or, in soln., by dissolving gallium in a little conc. hydrochloric acid. When the last-named soln. is diluted with water, a soln. of gallic chloride is formed, and bubbles of hydrogen gas are given off—the gas carries some entrained spray of the soln., hence the older suggestion that it is *gallium hydride*. The white or pale grey solid is very hygroscopic, and in air forms deliquescent crystals. The salt melts at 164°, and boils at 535°. The fused salt is readily under-cooled. According to L. F. Nilson and O. Pettersson, the vapour density between 1000° and 1100° is 4·82, and between 1300° and 1400°, 3·56—the theoretical value for $GaCl_2$ is 4·86. W. Hampe found the molten salt is a good electrical conductor—globules of metal separate at the cathode, but the chlorine at the anode converts the gallous into gallic chloride. According to L. de Boisbaudran, a little water dissolves gallous chloride, forming a syrup which has strong reducing properties; with further dilution, there is a vigorous evolution of hydrogen, and a brown gallous oxide is precipitated.

Gallic chloride is formed by the action of an excess of chlorine or hydrogen chloride on the metal at about 240°. The reaction is attended by the evolution of much heat. Good crystals were obtained by melting or subliming the product. L. M. Dennis and J. A. Bridgman, and T. W. Richards, W. M. Craig, and J. Sameshima found that the preparation of gallic chloride by burning gallium in dry chlorine, and distilling the product first in chlorine, then in nitrogen, and then in vacuo, gave a product whose spark spectrum showed it to be free from other metals. L. de Boisbaudran found the m.p. to be 75·5°; and the b.p., 210°–215°. The molten salt has a tendency to under-cooling, it is also readily superheated to 240°, and the liquid absorbs dry gases, rejecting them again on cooling. The soln. of chlorine in the superheated liquid is yellow. According to W. Hampe, the sp. gr. of the liquid at 80°/80° is 2·36. The vapour density of the gas has been determined by L. de Boisbaudran, C. Friedel and J. M. Crafts, and by L. F. Nilson and O. Pettersson, with the average results:

	237°	273°	307°	360°	440°	606°	1000°–1100°
Vapour density .	11·73	11·9	10·61	8·84	6·52	6·14	5·18

the calculated value for Ga_2Cl_6 is 12·16 and for $GaCl_3$, 6·08. W. Hampe found that fused gallic chloride is not such a good electrical conductor as gallous chloride, and no metal separates at the cathode "evidently owing to its entering into combination with gallic chloride to form gallous chloride." L. de Boisbaudran found that anhydrous gallic chloride is very hygroscopic; it fumes and deliquesces in air giving off hydrogen chloride. It dissolves in a little water with the evolution of much heat to form a non-crystallizable syrup; and in an excess of water, the salt is hydrolyzed, furnishing a white precipitate—oxychloride—which dissolves but slowly in dil. hydrochloric acid. A soln. of gallic chloride in dil. hydrochloric acid gives a precipitate—oxychloride—when boiled, and this redissolves as the soln. cools. If a slightly acid soln. of gallic chloride is dried at a gentle heat, it furnishes needle-like crystals and leaflets which act strongly on polarized light. Gallic chloride volatilizes slightly when repeatedly evaporated with hydrochloric acid, or aqua regia. C. Wilgerodt found that a little gallic chloride in benzene stimulates the chlorination of the benzene by chlorine.

A neutral or feebly acid soln. of gallic chloride slowly becomes turbid when allowed to stand for some time in the cold, and the reaction is rapid on heating. The product is considered by L. de Boisbaudran to be **gallic oxychloride.** He also found that a specimen of hydrated gallium chloride, prepared in 1878, and enclosed in a sealed tube, remained unaltered for some time, but was found in 1881 to have changed to a mass of small crystals, surrounded by a liquid which had a strongly acid reaction. The crystals were small octahedrons with truncated angles, and without action on polarized light. They are only slightly soluble in water or nitric acid, but dissolve slowly in hydrochloric acid, and immediately in potash. Analysis leads to the formula $6GaOCl.14H_2O$.

L. de Boisbaudran and E. Jungfleisch found that bromine acts on gallium less vigorously than chlorine. They prepared *gallous bromide*, or **gallium dibromide,** $GaBr_2$, and *gallic bromide*, or **gallium tribromide,** $GaBr_3$, by processes similar to those employed for the chlorides. The properties are analogous, but the bromide is less volatile. They also found that gallium must be warmed to start the reaction with iodine; they prepared an impure *gallous iodide*, or **gallium diiodide,** GaI_2, as a yellow crystalline mass which melts to a viscid red liquid, and *gallic iodide*, or **gallium triiodide** GaI_3, in colourless, needle-like crystals which readily sublime. Otherwise the iodides resemble the chlorides.

§ 8. Gallium Sulphides, Sulphates, and Nitrates

When hydrogen sulphide is allowed to act on a conc. soln. of gallic chloride in an ammoniacal soln. of ammonium tartrate, L. de Boisbaudran obtained a precipitate which he considered to be **gallic sulphide.** Hydrogen sulphide does not render turbid a slightly acid soln. of gallium chloride or sulphate; and no precipitate is obtained even if acid ammonium acetate is present. The case is quite different if a little zinc or other heavy metal is present. and L. de Boisbaudran[1] assumed, without proof, that the white precipitate formed by hydrogen sulphide in a soln. of gallium acetate containing a little zinc is a mixture of the two sulphides. He said:

> The precipitation of gallium sulphide by hydrogen sulphide in the presence of salts of zinc offers a rather curious instance of the effects which are produced in a very large number of chemical reactions. If the precipitated sulphides, obtained in soln. prepared by the successive addition of zinc chloride to a soln. rich in gallium, be examined by the spectroscope, it will be seen that they appear to remain at first almost constant, or at least to decrease slowly, then more and more rapidly until the ray $Ga\alpha$ 417·1 is no longer visible. Thus, the quantity of gallium precipitated by zinc sulphide does not seem to be a function of the conc. of the liquid. Within certain limits it seems to be almost in proportion to the amount of zinc sulphide formed. Is there not here an indication of a combination between the two substances, or perhaps more probably a surface-attraction analogous to the fixation of a colouring matter upon a mordant?

A. Dupré dissolved his gallium monoxide in sulphuric acid, and obtained a soln. which reduced permanganate, and which did not form an alum with ammonium sulphate. He therefore inferred that the soln. contained **gallous sulphate,** $GaSO_4$. L. de Boisbaudran prepared **gallic sulphate,** $Ga_2(SO_4)_3.nH_2O$, by dissolving the metal, the oxide, or the hydroxide in sulphuric acid. The slow evaporation of the aq. soln., or the cooling of a conc. soln., furnishes crystals in the form of leaflets having a pearly appearance, and sometimes grouped in stars or shining masses. The salt is very soluble in water; it is not deliquescent. A neutral aq. soln. decomposes on boiling, and if the soln. is sufficiently dilute, very little gallium remains in soln.; on cooling, the precipitate redissolves. If acetic acid be present, the boiling soln. does not become turbid. Gallic sulphate is soluble in 60 per cent. alcohol, but it is insoluble in ether. If the soln. be evaporated and dried until the evolution of white sulphuric acid vapour almost ceases, an acid gallic sulphàte is formed which does not lose its solubility in water or dil. alcohol, but it requires a long time to dissolve. If heated to redness, gallic oxide is formed. L. F. Nilson and O. Pettersson found the sp. ht. is 0·1460, and the mol. ht., 61·90.

L. de Boisbaudran prepared what he called *ammonia gallium alum*, $(NH_4)_2SO_4.Ga_2(SO_4)_3.24H_2O$, or dodecahydrated **ammonium gallic disulphate,** $NH_4Ga(SO_4)_2.12H_2O$, by crystallization from a mixed soln. of the component salts. It crystallizes in cubes having octahedral faces, and in octahedra with cubic faces. The crystals have no action on polarized light, and they resemble in all respects the crystals of other alums. The soln. can be readily obtained in a supersaturated state; and if a small crystal be kept for some time under water to deprive it of the crystalline germs attached to its surface, and then laid in a supersaturated soln. of ordinary ammonia alum, its growth is resumed, and it determines the crystallization of the liquid. C. Soret also prepared ammonia gallium alum, as well as *potash gallium alum*, $K_2SO_4.Ga_2(SO_4)_3.24H_2O$, or dodecahydrated **potassium gallic disulphate,** $KGa(SO_4)_2.12H_2O$; *rubidia gallium alum*, $Rb_2SO_4.Ga_2(SO_4)_3.24H_2O$, or dodecahydrated **rubidium gallic disulphate,** $RbGa(SO_4)_2.12H_2O$; and *cæsia gallium alum*, $Cs_2SO_4.Ga_2(SO_4)_3.24H_2O$, or dodecahydrated **cæsium gallic disulphate,** $CsGa(SO_4)_2.12H_2O$, by crystallization from a soln. of the component salts. C. Soret found the sp. gr. and the refractive indices, μ, of these four gallic alums, at 15°–25°, to be :

Gallic alum		NH_4	K	Rb	Cs
Sp. gr.		1·777	1·895	1·962	2·113
μ	*a*	1·46390	1·46118	1·46152	1·46047
	B	1·46485	1·46195	1·46238	1·46146
	C	1·46575	1·46296	1·46332	1·46243
	D	1·46835	1·46528	1·46579	1·46495
	E	1·47146	1·46842	1·46890	1·46785
	b	1·47204	1·46904	1·46930	1·46841
	F	1·47412	1·47093	1·47126	1·47034
	G	1·47864	1·47548	1·47581	1·47481

There was no optical anomaly with the potash and ammonia gallic alums; the refractive index of cæsia gallic alum is smaller than that of rubidia gallic alum, a result also observed with the chromic alums. The sp. refraction of rubidia gallic alum by J. H. Gladstone is 0·2318; the molecular refraction is 269·63; and the sp. dispersion is 0·077. L. de Boisbaudran found ammonia gallic alum is soluble in water and dil. alcohol. According to L. M. Dennis and J. A. Bridgman, at 25°, 100 c.c. of a sat. aq. soln. contain 30·84 grms. of ammonia gallic alum, or 1·51 grms. of cæsia gallic alum; or one part of the ammonia or cæsia salt dissolves respectively in 3·24 and 66·2 parts of water. One part of the ammonia or cæsia salt dissolves respectively in 4600 and 25,800 parts of 50 per cent. alcohol at 25°, or 100 c.c. of the soln. contain 0·0217 and 0·00387 grm. of the respective alums. One part of ammonia gallic alum dissolves in 11,400 parts of 70 per cent. alcohol at 25°, and one part of cæsia gallic alum in 28,000 parts of 70 per cent. alcohol, or 100 c.c. of the soln. contain 0·00875 and 0·00356 grm. of the respective alums. One part of ammonia or cæsia gallic alum dissolves respectively in 620 or 4380 parts of a soln. containing 30 c.c. of water, 50 c.c. of absolute alcohol, and 15 c.c. of conc. sulphuric acid at 25°. A conc. soln. of ammonia gallic alum becomes slightly turbid on boiling, and clears completely on cooling. When the soln. is very dil. the boiling causes the formation of an abundant white precipitate; this is probably a basic salt. If filtered when hot, only traces of gallium remain in the liquid. The precipitate may then be washed over the filter, at first with boiling, then with cold water, without sensible loss of gallium, but if it is left in contact with the mother liquor it is completely redissolved on cooling. The dil. soln. of gallium alum does not become turbid on boiling if a little sulphuric acid is added. A certain quantity of acetic acid produces the same effect; doubtless an equilibrium is then maintained between the ammonium acetate and the sulphate, and the small portion of sulphuric acid set at liberty holds the gallium sulphate in soln. If an aq. soln. be allowed to stand for some time in an open vessel, a basic salt is precipitated which rapidly dissolves in hydrochloric acid, and slowly in sulphuric acid.

Gallium carbonate has not been prepared. **Gallic nitrate,** $Ga(NO_3)_3$, is formed by dissolving the metal, oxide, or hydroxide in nitric acid; A. Dupré [2] prepared it by heating the metal with monohydrated nitric acid to 40°–50°. The nitric acid soln., after being deprived of a part of its acid over the open fire, was heated in a stove to 110°, when a commencement of decomposition was manifested. The salt, partly decomposed, was then taken up in water, evaporated to a syrup on the water-bath, and placed, whilst cooling, in a desiccator. The nitrate then forms a white compact mass, very deliquescent, and giving off an odour of nitric acid, which, as well as the moisture, may be removed in a vacuum, or in a current of dry air at 40°. The dry nitrate, heated to 200° in a current of dry air, loses 63·8 per cent. of its weight; gallic oxide remains. *Gallium phosphate* has not been studied.

CHAPTER XXXV

INDIUM

§ 1. The History and Occurrence of Indium

IN the summer of 1863, F. Reich and T. Richter[1] examined two zinc blendes from Freiberg. These ores had been freed from the greater part of their arsenic and sulphur by roasting, and the residue was evaporated to dryness with hydrochloric acid and distilled. The crude zinc chloride so obtained was examined with the spectroscope for thallium since that element has been previously found in similar ores from the Freiberg mines. Instead of the thallium lines, however, they obtained an indigo-blue line. After the crude product had been purified, the spectrum showed an intense indigo-blue line, and a second fainter blue line. The new metal was named *indium* from the indigo-blue lines of its spectrum. P. E. Browning has compiled a bibliography of the literature of this element.

Indium does not occur native. According to W. Vernadsky, and W. N. Hartley and H. Ramage, the element is widely distributed, but in very minute quantities. J. H. L. Vogt, and F. W. Clarke and H. S. Washington estimate that the ten-mile crust, the hydrosphere, and the lithosphere of the earth contain 0·0000000x per cent. of indium. It occurs in numerous zinc blendes. F. Reich and T. Richter reported 0·1 per cent., and T. Richter 0·025 to 0·04 per cent. in the blende from Freiberg; J. Kachler reported it in a blende from Schlaggenwald (Bohemia); N. S. Maskelyne, in a blende from Durham; C. Winkler found 0·0062 per cent. on christophite, a zinc blende from Breitenbrun (Saxony); H. B. Cornwall, F. L. Bartlett, and W. F. Hillebrand and J. A. Scherrer, in American zinc blendes; and C. Rimatori, in Sardinian zinc blendes to the extent of 0·1231 per cent. F. Reich and T. Richter found indium to follow the zinc in the extraction of the last-named element from its ores. C. Winkler found 0·0448 per cent.; and R. E. Meyer, 0·0142 per cent. G. Urbain examined the ultra-violet spectrum of 64 samples of zinc blende, and found indium to be present chiefly in those blendes containing little or no germanium. A. del Campo y Cerdan found indium in 37 of the 68 samples of zinc blende; in 29 cases he found gallium, indium, and germanium to be present; gallium and indium were present in 4 cases, and indium alone in one specimen. In no case did germanium and indium occur together in the absence of gallium. W. N. Hartley and H. Ramage have discussed the occurrence of indium in zinc blendes. R. Böttger found 0·1 per cent. of indium in the flue-dust of the Goslar zinc works; and A. Thiel, 0·2 per cent. in the flue-dust of the lead works at Clausthal. B. Delachanel and A. Mermet, P. E. Browning and H. S. Uhler, and A. Streng found indium in some zinc residues and furnace products. For an indium-gallium alloy from zinc furnaces —*vide* gallium. J. A. Tanner found indium to be contained in smithsonite from Virginia and Tennessee; A. and G. de Negri found it in calamine from Oriela (Bergamo); and J. B. Kirkland, in zinc ore from Peelwood (New South Wales). A. Thiel found indium in copper from Oker. F. Hoppe-Seyler found about 0·0228 per cent. of indium in wolframite from Zinnwald, but E. A. Atkinson did not find it in other wolfram ores. W. N. Hartley and H. Ramage examined about 168 samples of iron-ore bauxites, etc., and found indium to be present in thirty—notably the siderites, manganese ores, and tin ores. J. N. Lockyer found that indium lines are present in the solar spectrum.

§ 2. The Extraction of Indium

F. Reich and T. Richter [1] extracted indium from black blende from the Himmelfahrt mine of Freiberg, by the following process. The yield was 0·1 per cent.

Finely powdered blende is dissolved in nitric acid and the soln. treated with hydrogen sulphide. In this way copper, lead, arsenic, tin, cadmium, and molybdenum are precipitated, and then separated by filtration. The filtrate is afterwards treated with a large excess of ammonia by which the greater part of the zinc is separated in soln., and indium oxide and other metals precipitated. The washed precipitate is now dissolved in acetic acid, and this soln. again treated with hydrogen sulphides, whereby indium sulphide contaminated with some iron, zinc and manganese sulphide, is thrown down. This precipitate is dissolved in hydrochloric acid with a little nitric acid. excess of ammonia is again added, and the precipitate rapidly filtered and washed. It is advisable to repeat this operation in order to remove the last traces of zinc and manganese. On dissolving this second precipitate in acetic acid, and treating the soln. with hydrogen sulphide, a beautiful yellow precipitate of indium sulphide is obtained, which, however, still contains some iron. To separate this, the sulphide is again dissolved in hydrochloric acid, the soln. oxidized with nitric acid, and then, by the careful addition of ammonia or sodium carbonate, a small quantity of indium oxide and the iron may be thrown down. The filtrate from this precipitate on the further addition of ammonia yields pure hydrated oxide; or, if treated with sodium carbonate at a boiling heat, gives a pure indium carbonate.

L. de Boisbaudran noted that when zinc blende is roasted, most of the indium remains in the residue. C. Winkler roasted the blende to convert the indium and zinc into sulphates. The product was extracted with water, and the soln. boiled with zinc. The indium, copper, cadmium, lead, etc., are precipitated as metals. The indium is isolated as in the extraction of indium from zinc. A. R. von Schrötter, F. Stolba, P. Weselsky, C. Winkler, and E. Jungfleisch have also discussed processes for the extraction of indium from zinc blende.

T. Richter dissolved the indiferous zinc in hydrochloric acid, and treated the soln. as in the case of zinc blende. C. Winkler employed the following process:

The zinc was treated with a quantity of dil. sulphuric acid insufficient to dissolve all the metal; after standing some weeks, a spongy mass of lead, copper, arsenic, iron, indium, cadmium, and zinc remained. 10 kgrms. of metal gave 208 grms. of residue which contained 4·312 grms. of indium. The product was mixed with conc. sulphuric acid, and heated strongly so as to volatilize most of the acid. The resulting greyish-white mass was extracted with water. The sulphates of copper, cadmium, zinc, iron, and indium pass into soln. The addition of ammonia precipitates indium hydroxide contaminated with hydroxides of iron, zinc, and cadmium. The washed precipitate was dissolved in a little hydrochloric acid, the ferric iron reduced to ferrous chloride by sulphur dioxide, and the indium hydroxide precipitated from the soln. by barium carbonate. C. Winkler also separated the iron from the indium by treating the soln. with an eq. amount of sodium chloride, and evaporating it to dryness. The product was extracted with cold water, and the soln. treated with hydrogen sulphide. To eliminate the iron, it is necessary to dissolve the indium sulphide in hydrochloric acid, and repeat the operation a number of times. The soln. is finally treated with ammonia to precipitate indium hydroxide.

The separation of indium from indiferous zinc has been discussed by R. E. Meyer, and H. Rossler and C. Wolf; from the flue-dust of zinc furnaces, by R. Böttger, F. L. Bartlett, and C. Winkler; and from the flue-dust of lead furnaces, by A. Thiel. C. J. Bayer obtained the oxide by treating indiferous zinc with insufficient hydrochloric acid to dissolve the metal. After standing for some days, the spongy residue is washed, dissolved in nitric acid, and the soln. evaporated with a slight excess of sulphuric acid. When the filtered soln. is treated with ammonia, indium and ferric hydroxides are precipitated. The washed precipitate is dissolved in hydrochloric acid, and the nearly neutral soln. boiled with an excess of sodium hydrosulphite; a fine crystalline powder of basic indium sulphite is precipitated. The product is purified by dissolving it in sulphurous acid, and on boiling the filtered soln. the basic sulphite free from iron is again precipitated. The basic sulphite is dissolved in sulphuric acid, and indium hydroxide precipitated by the addition of ammonia. F. C. Mathers dissolved the impure hydroxide in hydrochloric acid; mixed the soln. with ammonium chloride; and precipitated with ammonia. Three or four repetitions of the operation remove the zinc, an excess of potassium thiosulphate was added to the hydrochloric acid soln., and the mixture extracted with ether. Ferric thiocyanate was removed. The aq. soln. was treated with ammonia for indium hydroxide. C. Renz, and L. M. Dennis and W. C. Geer separated indium from iron and aluminium chlorides by treating an alcoholic soln. of the anhydrous chloride with pyridine when a colourless precipitate of indium pyridine chloride, $InCl_3.3C_5H_5N$, was obtained; the iron and aluminium chlorides remained in soln. A. Thiel purified the oxide by transforming it into the bromide, $InBr_3$, and subliming the product in a stream of carbon dioxide the ferrous bromide remains behind. A. Thiel, and F. C. Mathers also purified indium by the fractional electrolysis of a soln. feebly acidified with nitric acid.

F. Reich and T. Richter, R. Bottger, and C. Winkler found that indium oxide can be reduced to the metal by heating it in a stream of hydrogen, or coal gas. C. Winkler obtained the metal by heating the oxide with sodium under a layer of sodium chloride. If the metal be reduced with sodium, the alloy of sodium and indium is decomposed by water, and the remaining indium is fused under a layer of sodium carbonate, or potassium cyanide; he did not recommend reducing the chloride with sodium, because of the violence of the reaction. If the oxide be reduced by heating it with carbon, so high a temp. is required that some metal is lost by volatilization. H. Rössler and C. Wolf precipitated indium by placing zinc in a soln. of the chloride. L. Schucht obtained indium by the electrolysis of soln. of the sulphate. L. M. Dennis and W. C. Geer found that indium is readily precipitated by the electrolysis of a soln. of the chloride or nitrate in pyridine, hydroxylamine, or formic acid; if oxalic acid or oxalates are present, the precipitation is incomplete; and in the presence of acetates, the deposited metal is spongy. They recommend the following process: Indium oxide is dissolved in the calculated quantity of 6*N*-sulphuric acid, and mixed with 25 c.c. of formic acid of sp. gr. 1·2, and 5 c.c. of aq. ammonia, sp. gr. 0·908. The soln. is made up to 200 c.c. and electrolyzed with a current of 9–12 amp. In the absence of formic acid, the platinum cathode is attacked. A. Thiel electrolyzed a soln. feebly acidified with nitric acid with a current of 0·8 amp. at 3 volts to precipitate the copper, lead, and antimony; after adding some ammonium sulphate, indium is deposited with a current of 5 volts. L. G. Kollock and E. F. Smith determined indium by deposition with a mercury cathode, or from warm cyanide or tartrate soln. with a rotating anode.

§ 3. The Physical Properties of Indium

F. Reich and T. Richter[1] found indium to be a silver-white metal with a **colour** which C. Winkler likened to that of platinum. T. Carnelley discussed the relation between the colour of indium compounds and the position of the metal in the periodic table. A. Thiel and A. Sachs found that the electro-deposited metal furnishes octahedral **crystals** belonging to the cubic system. The crystals are isomorphous with gallium and aluminium, but not with zinc. According to E. C. Bain, and A. W. Hull, the **X-radiogram** of indium corresponds with that of the face-centred tetragonal lattice with sides 4·58 A., and closest approach of the atoms 3·33 or 3·24 A. According to F. Reich and T. Richter, the **specific gravity** of the metal which has been fused is 7·128 at 20·4°, while the rolled metal has a sp. gr. 7·277 at 20·4°. A. Ditte gave 7·15, and C. Winkler 7·362 (15°) for the sp. gr. of the metal; C. Winkler later gave 7·421 at 16·8°, and 7·422 for the hammered metal. A. Thiel found the sp. gr. of the crystals to be 7·12 at 13°/4°. T. W. Richards and J. H. Wilson gave 7·277 at 20°; and T. W. Richards and J. Sameshima, 7·310 at 20°; E. Donath and J. Mayrhofer discussed the at. vol. C. Winkler said that the melted metal can be frozen in a thin-walled glass tube without cracking the tube or showing any appreciable change in volume; he also said that the metal is much softer than lead, very ductile, and can be rolled to the thinnest foil. S. Bottone represented the **hardness** by 0·0984 on his scale; for lead his value is 0·057. C. A. Edwards gave 1·0 for Brinell's hardness; and 1·28 for the **plasticity** number when that of copper is 49·3. A. Thiel found that the metal is soft enough to yield under pressure by the fingers. W. C. Roberts-Austen found the **tensile strength** of indium with 0·29 per cent. of impurity to be 7·99 tons per sq. in.; the elongation on 3 ins., 26·5 per cent.; and the reduction of area at the fracture, 72 per cent. N. S. Kurnakoff and S. F. Schemtschuschny gave 3·06 kgrms. per sq. mm. for the flowing press. T. W. Richards and J. Sameshima found the **compressibility** of indium at 25° over a range from 100 to 500 megabars, to be 0·0000027, or about two-thirds that of mercury. H. Fizeau found the coeff. of **thermal expansion** to be 0·0000459. According to C. Winkler, the **melting point** is 176°, while A. Thiel gave 155° ± 1°—and W. R. Mott, 155·0°—W. Guertler and M. Pirani give this as the best representative value. According to C. Winkler, indium is less volatile than zinc or cadmium, and it shows no signs of **volatilization** when heated to the softening temperature of glass in a stream of hydrogen. A. R. von Schrötter sublimed the metal by heating it in a stream of hydrogen; and J. N. Lockyer, by heating it in vacuo. A. Ditte said the metal boils at a red heat. W. R. Mott gave 1450° for the **boiling point.** M. Lémeray, and H. F. Wiebe studied the relation between the m.p. and the thermal expansion. R. Pohl and P. Pringsheim made mirrors of indium by condensing the vapour on quartz plates. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of sodium by indium. R. W. Bunsen gave 0·05695 for the **specific heat** between 0° and 100°; D. I. Mendeléeff found 0·055. A. Ditte gave the value 37·502 Cals. for the **heat of combustion** of one eq. of indium.

According to F. Reich and T. Richter, the Bunsen flame is coloured bluish-red by indium salts and the **flame spectrum** gives two lines 4511·55 and 4101·95, Fig. 1,

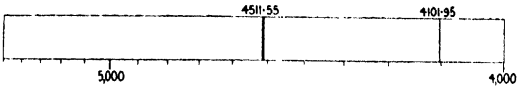

FIG. 1.—Line Spectrum of Indium.

which lie close to the violet potassium line. The 4101·95 line, however, is observed only when a large excess of indium is present. The flame spectrum does not persist very long because of rapid volatilization in the gas-flame. The spark spectrum furnishes these two lines, and in addition a number of other lines, the more important of which are 3256·22, 3039·46, 2941·39, 2890·35, 2710·39, 2306·20, etc. W. N. Hartley and H. Ramage observed a band spectrum in the oxy-hydrogen flame. According to E. Cappel, $\frac{1}{90000}$th mgrm. of indium can be detected from the **spark spectrum** of a soln. S. Wleügl said that $\frac{1}{3000}$th mgrm. is the smallest amount of indium which can be recognized spectroscopically. F. Hoppe-Seyler discussed the testing of minerals for indium by means of the spectroscope. Photographs of the spectra have been made by R. Capron, W. N. Hartley, etc. The flame spectrum has been studied by L. de Boisbaudran, W. N. Hartley and H. Ramage; the spark spectrum, by A. de Gramont, W. Schulemann, A. Hagenbach and H. Konen, A. R. von Schrötter, J. Müller, C. Winkler, R. Thalén, L. de Boisbaudran, A. W. Clayden and C. T. Heycock, W. N. Hartley, E. Demarçay, F. Exner and E. Haschek, and J. M. Eder and E. Valenta; the **arc spectrum,** by H. Kayser and C. Runge, H. S. Uhler and J. W. Tanch, F Exner and E. Haschek; and the **ultra-violet spectrum,** by F. Exner and E. Haschek, J. L. Schönn, etc. The **series spectra** were studied by A. Fowler, and J. A. Carroll. The effect of *temperature* has been investigated by E. Cappel; and the effect of *pressure* by J. F. Mohler, and W. J. Humphreys. The **absorption spectrum** of the vapour of indium has been studied by J. N. Lockyer and W. C. Roberts-Austen, and W. Grotrian. G. D. Liveing and J. Dewar. According to J. Formanek, soln. of colourless indium salts give no absorption spectrum; but if the soln., not too dil., is mixed with tincture of alkanna, the colour gradually becomes reddish-violet, and bands appear about 5961, 5537, and 5168. The **structure of the spectrum** has been studied by H. Kayser and C. Runge, W. Grotrian, P. G. Nutting, W. M. Hicks, F. Paschen and K. Meissner, etc. According to the former, the two subordinate series have the pairs of lines $10^8\lambda^{-1}=44515·4-13908n^{-2}-1311032n^{-4}$; $10^8\lambda^{-1}=46728·6-139308n^{-2}-1311032n^{-4}$; and $10^8\lambda^{-1}=44535·0-126766n^{-2}-643584n^{-4}$; $10^8\lambda^{-1}=46748·2-126766n^{-2}=643584n^{-4}$. The relations between the spectra of aluminium, indium, and thallium are illustrated by Figs. 26 and 27, **5.** 33, 4. E. Friman studied the high frequency or **X-ray spectrum.** F. C. Blake and W. Duane, and M. Siegbahn gave in Angström units, or 10^{-8} cm. units; for the *K*-series, $\alpha_2\alpha'=0·515$; $\alpha_1\alpha=0·510$; $\beta_1\beta=0·453$; and $\beta_2\gamma=0·440$; for the L-series, D. Coster, E. Hjalmar, and M. Siegbahn gave $\alpha_2\alpha=3·77242$; $\alpha_1\alpha=3·76367$, $\alpha_3\alpha''=3·74991$; $\beta_1\beta=3·54783$; $\beta_2\gamma=3·332$; and $\gamma_1\delta=3·15529$. R. Pohl and P. Pringsheim studied the **photoelectric effect** of indium. F. L. Mohler and A. E. Ruark gave for the **ionization potential,** $2p_2=5·761$, and $2p_1=5·488$; and for the **resonance potential,** $2p_2-2p_1=0·273$; $2p_2-2s=3·009$; and $2p_2-3d_{1,2}=4·06$.

The **atomic refraction** of indium in combination was found by J. H. Gladstone to be 13·7, and later he gave 17·4. T. Erhard found the **specific resistance,** *R*, of indium wires to be $8·37\times10^{-6}$ ohms at 0°; and A. W. Smith gave:

	Solid				Liquid			
	24·1°	80·4°	121·4°	142·7°	154·0°	181·5°	222·0°	280·2°
$R\times10^6$ . .	9·27	11·48	13·09	14·63	29·10	30·11	31·87	34·87

or $R=0{\cdot}08903(1+0{\cdot}004744\theta)$ mercury units. There is a break in the curve in passing from the liquid to the solid state, and the resistance of each varies linearly with the temp., and is less with the liquid than with the solid. H. Schulze, and T. Erhard found $4{\cdot}77\times10^{-3}$ for the temp. coeff., $(dR/d\theta)R_0$, of the resistance of indium between $-5{\cdot}4°$ and 96°; and they gave $R=8{\cdot}370\times10^{-6}(1+0{\cdot}004744\theta)$. P. W. Bridgman found $4{\cdot}07\times10^{-3}$; and A. W. Smith gave $5{\cdot}24\times10^{-3}$ for the temp. coeff. of the solid, and $3{\cdot}98\times10^{-3}$ for that of the liquid. W. Tuyn and H. K. Onnes showed that the metal becomes superconducting in the vicinity of 3·407° K. to 3·409° K. P. W. Bridgman observed that with indium under different press. the press. coeff. of the electrical resistance is:

		Pressure coefficient		
	R	0 kgrm	12000 kgrms. per sq cm	Average
0° . .	1·0000	$-0{\cdot}0_41226$	$-0{\cdot}0_5891$	$-0{\cdot}0_41021$
25° . .	1·1002	1297	896	1051
50° . .	1·2015	1368	911	1081

This shows that the average press. coeff. increases linearly with temp., but the increase is less than one-third as much as the increase of resistance; the departure from linearity increases at the higher temp. more rapidly than the initial resistance.

T. Erhard found that the **thermoelectric force** of indium soldered with different metals when the temp. of the cold and hot junctions are respectively 0° and 98·6°, is in the order —Al, Sn, **In,** Zn, Ag, Au, Cu, Fe+; while with the cold and hot junctions respectively 0° and 5° or 10°, the order is —Al, Sn, Au, Zn, **In,** Ag, Cu, Fe+. Indium is electronegative to zinc, and electropositive towards iron and copper; A. R. von Schrötter found indium to be more electronegative than zinc or cadmium; and A. Thiel said that the **solution pressure** of indium is from 10^2 to 10^3 atm., being between that of iron and of lead. T. Erhard found that the **electromotive force** of the cell In | $InCl_3$, MCl_2 | M, is 0·381 Daniell units for M=Zn; 0·160 for M=Fe; and 0·584 for M=Cu. A. Thiel measured the potential of indium—with a decinormal calomel electrode 0·620 volt—against molar, tenth-molar, and hundredth-molar soln. of indium chloride, and found it to be respectively 0·094, 0·108, and 0·119 volt at 25°. The metal is negative to the soln. According to M. Owen, indium is diamagnetic; and K. Honda said that the **magnetic susceptibility** at 18° is about $-0{\cdot}1\times10^{-6}$ mass units.

§ 4. The Chemical Properties of Indium

According to J. N. Lockyer,[1] when indium is heated in vacuo, occluded **hydrogen** is evolved. No *indium hydride* has been found. C. Winkler stated that when indiferous hydrochloric or sulphuric acid is treated with zinc, the evolved hydrogen does not burn with an indium-coloured flame, nor when the gas is obtained by the action of the acid on indiferous zinc or on indium. F. Reich and T. Richter found that if indium oxide is reduced by hydrogen, the issuing gas burns with a violet-blue flame; according to C. Winkler, the coloration persists if the gas be passed through dil. acids; and if the gas be confined over water for some hours, a grey film is deposited on the walls of the vessel, and the gas then burns without giving the coloration. It is probable that these effects are produced by particles mechanically suspended in the gas. The blue colour acquired by indium sesquioxide, In_2O_3, when partially reduced in a stream of hydrogen, is attributed by A. Thiel to the formation of an intermediate oxide, InO or In_2O.

According to F. Reich and T. Richter, indium retains its lustre in **air** and even under boiling **water.** A. Thiel found that when the metal in contact with water is exposed to air, some hydroxide is formed in a few hours. The metal, however, is not affected by dry air at ordinary temp. Indium retains its lustre when heated to a temp. a little above the m.p., a film of the monoxide is then formed, and at a still higher temp., the sesquioxide is formed: at a red heat, in air, or oxygen. A. Ditte found that indium burns with a blue flame, forming indium trioxide, In_2O_3. Indium unites directly with the **halogens** when warm; and when heated with **sulphur,** the elements unite with incandescence. F. Reich and T. Richter found that indium dissolves slowly in cold dil. **mineral acids,** but more rapidly when heated - hydrogen is evolved and a salt of the metal formed. According to C. Winkler, with conc. **sulphuric acid** in the cold, hydrogen is evolved and anhydrous indium sulphate separates out; with hot conc. sulphuric acid, sulphur dioxide is evolved; with conc. **hydrochloric acid,** the metal rapidly dissolves with the evolution of hydrogen. According to C. Winkler, the action of cold **nitric acid** is slow, rapid when heated, and nitric oxide is evolved. According to J. J. Ackworth and H. E. Armstrong, ammonia is found among the products of reduction with nitric acid. Indium is not attacked by a soln. of potassium hydroxide. According to C. Winkler, **acetic acid** does not dissolve indium, but it is dissolved by a soln. of **oxalic acid.**

C. T. Heycock and F. H. Neville found that indium readily alloys with **sodium;** and W. C. Roberts-Austen, with **gold.** T. W. Richards and J. H. Wilson prepared **indium amalgams** and measured the sp. gr. at 20°, and the potential of conc. cells. J. H. Hildebrand studied the vap. press. of these amalgams. L. de Boisbaudran studied alloys of **gallium** and indium in the atomic proportions, In : Ga=2 : 1, 1 : 1, 1 : 2, and 1 : 4. P. E. Browning and H. S. Uhler obtained an alloy of sp. gr. 5·95 at 20°; m.p. 29·5°; and when heated in vacuo at 1600°, the indium distils off. The alloy is only slightly attacked by acids, or alkali-lye. N. S. Kurnakoff and N. A. Puschin studied the alloys of **lead** and **tin** ; and A. Thiel noted that when indium is electrolytically deposited on **platinum** an alloy is formed.

Many indium salts are readily formed by dissolving the oxide, hydroxide, or carbonate in acids. According to L. F. Nilson and O. Pettersson, indium behaves as a bi- and ter-valent element; some ill-defined univalent indium salts—halides, oxide, and sulphide—have been reported. The tervalent indium salts are alone stable in aq. soln., and, according to A. Thiel, the indium salts are much hydrolyzed in aq. soln., but to a less extent than gallium, showing that tervalent indium forms a stronger base than gallium. A. Ditte said that zinc and indium are related very intimately—the two metals occur together, and they resemble one another very closely in their analytical reactions—and in emphasizing this relationship, F. Reich and T. Richter stated that they had failed to prepare an alum, but C. Soret, P. C. Chabrié and E. Rengade, and H. Rössler showed that indium alums can be readily formed.

Reactions of analytical interest.—Indium sulphate, nitrate, and chloride are colourless solids readily soluble in water. According to F. Reich and T. Richter, and C. Winkler, when the aq. soln. of an indium salt is treated with a soln. of **potassium or sodium hydroxide,** or **ammonia,** white indium hydroxide, $In(OH)_3$, is precipitated; the presence of tartaric acid retards the precipitation, but G. Wyrouboff noted the precipitation by alkalies does occur even in the presence of an excess of tartaric and similar acids. C. Winkler, and F. Reich and T. Richter found that the precipitate is peptized to a turbid liquid when treated with a soln. of potassium or sodium hydroxide, and when the alkaline soln. is boiled, or when treated with ammonium chloride, indium hydroxide is precipitated. The precipitate is not dissolved by aq. ammonia. According to A. Thiel and H. Kölsch, in quantitative work the precipitated hydroxide is best heated in the blast gas-flame, and weighed as sesquioxide. According to C. Renz, indium salts, like those of zinc, magnesium, and copper, are quantitatively precipitated by heating with **organic bases** like dimethylamine, guanidine, and piperidine; and L. M. Dennis and W. C. Geer obtained gelatinous indium hydroxide by treatment with a soln. of **hydroxylamine.** J. F. Spencer and M. L. Wallace found that the reaction of indium salts with **organic halides** is slower than is the case with aluminium salts. According to C. Winkler, and F. Reich and T. Richter, white gelatinous indium carbonate is precipitated by a soln. of **sodium or ammonium carbonate;** the precipitate is soluble in an excess of a soln. of ammonium carbonate, but when the soln. is boiled, indium carbonate is re-precipitated; it is not soluble in a soln. of potassium or sodium carbonate. **Sodium hydrocarbonate** behaves like the normal carbonate. When a cold soln. of an indium salt is digested with **barium carbonate,** a basic carbonate of indium is precipitated, and this enables indium to be separated from zinc, manganese, cobalt, nickel, and ferrous salts. According to C. Winkler, a soln. of **sodium hydrophosphate** gives a white voluminous precipitate which forms a turbid soln. with potassium hydroxide lye; **oxalic acid** and the **alkali oxalates** added to a conc. neutral soln. give a crystalline precipitate; R. E. Meyer found **sodium succinate and formate** behave towards neutral indium salt soln. as in the case of ferric salts—precipitation begins with the formate in the cold. According to F. Reich and T. Richter, **potassium ferrocyanide** gives a white precipitate, and **potassium chromate** a yellow precipitate; but no precipitation occurs with soln. of **potassium ferricyanide, thiocyanate, or dichromate.** When a soln. of an indium salt is mixed with **sodium acetate,** and boiled, basic indium acetate is precipitated. F. Reich and T. Richter, and C. Winkler found that when a neutral soln. of an acetic acid soln. of an indium salt is treated with **hydrogen sulphide,** all the indium is precipitated as yellow sulphide, In_2S_3; soln. strongly acidified with mineral acids do not give a precipitate until they are diluted. When an alkaline soln. of an indium salt is treated with hydrogen sulphide, or when a neutral soln. is treated with **ammonium sulphide,** a white precipitate of indium hydrosulphide, or ammonium indium sulphide is formed; yellow indium sulphide becomes white and partially dissolves when boiled with yellow ammonium sulphide, and, on cooling, the soln. deposits the white precipitate. According to R. E. Meyer, colourless ammonium sulphide does not dissolve the hydrosulphide; similarly, **potassium hydrosulphide,** KHS, in excess does not dissolve the precipitate, but **potassium monosulphide,** K_2S, gives a yellow precipitate with soln. of indium salts, and the precipitate forms a colourless soln. with an excess of the reagent. This soln. is not changed by acetic acid, but a little hydrochloric acid precipitates the yellow sulphide, which dissolves when more acid is added; sulphur dioxide precipitates from the soln. white hydrosulphide mixed with some sulphur; boiling does not alter the soln.; and exposure to air results in the oxidation of the potassium monosulphide, and the precipitation of yellow sulphide. According to C. Winkler, when **sodium thiosulphate** is treated with a neutral soln. of an indium salt, a precipitate of indium sulphite and sulphur is formed, and when boiled, a basic sulphate is formed; with acid soln., sodium thiosulphate forms yellow indium sulphide, but most of the indium remains in soln.; and with acetic acid soln., all the indium is precipitated as basic sulphate. O. Brunck found **sodium hyposulphite** gives no precipitate with acid soln. of indium salts, but when boiled with neutral soln., yellow indium sulphide is precipitated. According to R. E. Meyer, **hydrocyanic acid** precipitates no cyanide from soln. of indium sulphate and the behaviour thus differs from soln. of zinc and cadmium salts; **potassium cyanide** gives a white precipitate, soluble in excess; by much dilution, the soln. is decomposed after some time, and indium hydroxide is precipitated when the dil. soln. is boiled; conc. soln. are coloured brown by this treatment owing to the formation of decomposition products of the cyanide. According to F. Reich and T. Richter, indium is precipitated from its salt soln. by **zinc** or **cadmium.** F. C. Mathers obtained a quantitative separation from iron by precipitation of the latter with **nitroso-β-naphthol.** A. C. Huysse used the ready formation of octahedral crystals of cæsium indium alum as a *microchemical test;* and P. Kley, the formation of crystals of the double chloride of indium and rubidium or cæsium. The analytical reactions of indium have been studied by I. Wada and S. Ato.[2]

The atomic weight of indium.—In 1864, J. A. R. Newlands[3] predicted that when the eq. of indium is determined, it will be found to bear a simple relation to the elements of the group to which it will be assigned. F. Reich and T. Richter shortly afterwards obtained the value 76 on the assumption that the metal is a dyad, but D. I. Mendeléeff and L. Meyer argued that the metal must be a triad, at. wt. 114, if it is to fit naturally in the periodic table; and L. Meyer showed that if indium is a triad it likewise fits the at. vol. curve. The sp. hts. also fit Dulong and Petit's rule if the element be a triad. The indium alums are isomorphous with the corresponding alums of aluminium, gallium, and thallium. L. Benoist found that the transparency of the elements to the X-rays is independent of its state of aggregation, or temp., and whether the element is free or combined; and when the eq. transparencies of the elements are plotted against the at. wt., a hyperbolic curve is obtained. R. Benoist found that with an at. wt. about 114, the eq. transparency of indium obtained by observations on the free element and on indium acetylacetonate, fitted in the curve. The spectroscopic method of C. Runge and J. Precht for estimating at. wt. by plotting the ordinates as logarithms of the at. wt., and the logarithms of distances apart of *the pairs of series spectral lines gave* W. M. Watts an at. wt. approximating 114—*vide Figs. 26 and 27,* **5**. *33, 4. F. L. Nilson and O. Pettersson* determined the vapour *density of the chlorides, and obtained results in agreement with the mol. formulæ* $InCl$, $InCl_2$, and $InCl_3$. According to Avogadro's rule, this makes the at. wt. of indium nearly 115. P. C. Chabrié and E. Rengade found that the raising of the b.p. of soln. of indium acetylacetonate, $In\{(CH_3CO)_2 : CH\}_3$, in ethylene bromide gave a mol. wt. 405 when the theoretical value for tervalent indium is 410. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of sodium, tin, lead, and bismuth by indium; the result with tin corresponded with a diatomic molecule, In_2; and the result with sodium, with a monatomic molecule, In. It is assumed that no complexes are formed. From the change in the electrical resistance and the thermal expansion, W. Broniewsky inferred that the molecule of indium is polyatomic. T. W. Richards and J. H. Wilson studied the e.m.f. of conc. cells of indium amalgam, and inferred that the metal is dissolved mainly in the monatomic form, though J. H. Hildebrand inferred that the solute is mainly $InHg_n$—probably $InHg_4$.

F. Reich and T. Richter first determined the at. wt. of indium by dissolving weighed quantities of the metal in nitric acid, precipitating the soln. with ammonia and igniting the washed precipitate. From the ratio $2In : In_2O_3$ they obtained the value 111·2; and by dissolving indium sulphide in nitric acid, and precipitating the sulphate as barium sulphate, they calculated 112·0 from the ratios $In_2S_3 : In_2O_3 : 3BaSO_4$. Both results are too low. Soon afterwards, C. Winkler dissolved the metal in nitric acid, evaporated the soln. to dryness, ignited the residue, and obtained indium trioxide; from the ratio $2In : In_2O_3$, he computed the at. wt. 113·44; R. Bunsen similarly obtained 113·84; and A. Thiel, 113·73–114·01. The last-named showed that this method is not reliable because the oxide retains gaseous inclusions, and is slightly volatile. C. Winkler precipitated gold from a soln. of sodium chloroaurate, by means of indium, and from the ratio In : Au, computed the at. wt. 114·03. A. Thiel then analyzed the indium halides; from the ratio $InCl_3 : 3AgCl$, he computed the at. wt. 115·01; and from $InBr_3 : 3AgBr$, the at. wt. 114·83; and from the ratios $In \cdot InCl_3$ and $In : InI_3$ he obtained respectively 115·4 and 115·3. F. C. Mathers obtained 114·834 from the ratio $InCl_3 : 3AgCl$, and 114·803 from $InBr_3 : 3AgBr$. A. Bilecky, S. E. Phillips, and G. D. Hindrichs discussed the at. wt. of indium. F. W. Clarke computed 114·864 ± 0·0040 for the best representative value; B. Brauner, 114·8; and the International Table gives 114·8. The **atomic number** is 49. F. W. Aston obtained no **isotopes,** for the element gave only one mass-spectral line corresponding with an at. wt. 115; the faint evidence of an isotope was not conclusive. According to G. Kirsch and H. Pettersson, when indium chloride is bombarded with α-rays from radium-c, no long-range particles indicating atomic disintegration are evolved; L. F. Bates and J. S. Rogers made observations on this subject.

§ 5. The Oxides of Indium

Indium oxidizes when heated above its m.p., and C. Winkler[1] showed that at a red heat it burns with a violet flame, forming brown flakes which deposit on the walls of the vessel as yellow **indium trioxide,** In_2O_3, or *indium sesquioxide*; the flakes are denser than the *lana philosophica* obtained by the combustion of zinc. F. Reich and T. Richter obtained this oxide by calcining the hydroxide or the carbonate; C. Winkler, by calcining the nitrate or one of the lower oxides; and C. J. Bayer, by calcining the sulphite. The oxide prepared by calcining the nitrate retains some nitric oxide very tenaciously, and J. Meyer, and A. Thiel removed the gas by treating the oxide with water and calcining it at 950°–1050°.

The **colour** of the oxide prepared by F. Reich and T. Richter, and C. Winkler was reddish-brown when hot, and a paler colour when cold; A. Thiel said the colour is yellow like chlorine, and a darker coloration shows that ferric oxide is present. According to C. Renz, the oxide occurs in two forms (i) a yellow, non-crystalline, compact or powdered mass, soluble in acids; (ii) yellow trigonal **crystals** very resistant towards acids. The latter form is produced at a high temp. Boiling with sulphuric acid is a good means of separating the two forms. The trigonal crystals are isomorphous with those of ferric oxide. Needle-like crystals were obtained by A. Thiel by calcining the nitrate at a high temp. The **specific gravity** is 7·179. C. Renz said that it melts with great difficulty. J. Meyer said that the **volatilization** of the oxide begins at 900°, and the rapidity of volatilization increases as the temp. rises, but after 10 hrs. at 1100° only about 0·01 per cent. was lost. A. Thiel said that the freshly prepared oxide is more volatile at 1000°–1450°, than if the oxide has been previously calcined. C. Renz found that the calcined oxide contains many isotropic crystals which were assumed to be those of cubic **indiosoindic oxide,** In_3O_4; isomorphous with ferrosoferric oxide, Fe_3O_4. A. A. Read observed no change when indium oxide in a lime crucible is heated by the tip of an oxy-coal gas flame. A. Thiel and H. Kölsch showed that the alleged volatility of indium oxide, determined by the loss in weight on calcination, is really due to the loss of oxygen, $3In_2O_3=2In_3O_4+O$. L. F. Nilson and O. Pettersson found the **specific heat** between 0° and 100° to be 0·0807. A. Ditte gave for the **heat of formation,** $(2In, 3O)=239·8$ Cals.; and for the **heat of neutralization,** $In_2O_3+3H_2SO_{4aq.}=In_2(SO_4)_{3aq.}+3H_2O+72·78$ Cals. K. Angstrom, and L. F. Nilson and O. Pettersson said that the oxide is diamagnetic.

According to C. Winkler, when indium trioxide is heated to 300° in a stream of **hydrogen,** it acquires a black colour and the action then stops. The powder gives up no metal to mercury. It is assumed that the trioxide is reduced to **indium dioxide,** In_2O_2, or InO. C. Winkler also claimed to have produced intermediate oxides, In_7O_9, In_4O_5, In_7O_6, and In_6O_5, by heating the trioxide in hydrogen to different temp. There is, however, very little to justify the inference that definite compounds are in question. C. Winkler, and A. Thiel found that when indium oxide is heated with **sulphur** or **hydrogen sulphide,** indium trisulphide, In_2S_3, is formed. L. M. Dennis and W. C. Geer found that dry **ammonia** gas reduces the oxide at 200°–300° with some volatilization, as observed by A. Thiel. The latter found that the calcined oxide dissolves slowly in cold **acids,** but more rapidly when warmed. Hot dil. **sulphuric acid** is a good solvent. F. Reich and T. Richter found that the oxide is reduced by **carbon** in a stream of hydrogen, but, according to C. Winkler, the metal beads coalesce to a button only when a flux is present. C. Winkler reduced the oxide by heating it with **sodium** or with **magnesium.**

When indium salt soln. are treated with aq. ammonia or alkali-lye, F. Reich and T. Richter obtained gelatinous **indium hydroxide,** $In(OH)_3$. R. E. Meyer found the precipitate to be soluble in an excess of alkali-lye, but again to separate from the soln. on boiling or standing; the hydroxide is but slightly soluble in aq. ammonia. L. M. Dennis and W. C. Geer found that a similar precipitate is obtained with a soln. of hydroxylamine, but not with hydroxylamine hydrochloride. C. Renz found the simple aliphatic primary and secondary amines also precipitate the hydroxide. C. J. Bayer obtained a similar precipitate by boiling a soln. of indium chloride with potassium nitrite. R. E. Meyer used the reaction with potassium cyanide—*vide supra*—in order to prepare the hydroxide free from iron. The air-dried precipitate was found by C. Winkler to have the composition $10In(OH)_3.3H_2O$; and when dried at 100°, $In(OH)_3$. T. Carnelley and J. Walker found that the air-dried precipitate lost water at a rate nearly uniform up to 150° when its composition was $In(OH)_3$; and the rate of loss at a higher temp. increased until the composition was InO(OH), without giving any evidence of the formation of a stable hydrate. Soon after passing 250°, the rate of loss abruptly diminished, and the curve became nearly vertical, showing that the last traces of water are lost very slowly. Complete dehydration occurred at 650°. The hydroxide was found by F. Stolba to be insoluble in a boiling soln. of ammonium chloride; C. Renz noted that it behaves towards amines like ferric hydroxide. P. C. Chabrié and E. Rengade noted that when indium hydroxide is heated with acetyl acetone, prismatic crystals of **indium acetylacetonate,** $In\{CH:(CH_3COO)_2\}$, are formed, and A. Thiel observed that the hydroxide is insoluble in ethylamine in the presence of chlorohydrates, and this enables it to be separated from aluminium hydroxide. A. Thiel also noted the analogy in the behaviour of precipitated indium and aluminium hydroxides in forming colloidal soln. when washed free from electrolytes. The soln. in aq. ammonia and dimethylamine are colloidal.

Indium hydroxide has basic properties, for, when treated with acids, salts are formed; it also possesses the properties of a weak acid, furnishing a series of **metaindates** which can be regarded as salts of monobasic **metaindic acid,** InO(OH), or $HInO_2$. For example, C. Renz obtained **magnesium metaindate,** $Mg(InO_2)_2$, by boiling an excess of magnesia with an aq. soln. of indium trichloride, decanting the soln., and washing the precipitate with a soln. of ammonium chloride. The white powder is insoluble in water, but soluble in hydrochloric acid.

§ 6. Indium Halides

A. Thiel[1] prepared colourless rhombic pyramids of **trihydrated indium trifluoride,** $InF_3.3H_2O$, by the evaporation on a water-bath of a soln. of indium sesquioxide in dil. hydrofluoric acid. These crystals are said to be almost dehydrated by a prolonged heating at 100°. The crystals are strongly doubly refracting. A litre of water at 25° dissolves 84 grms. of the salt. The aq. soln. decomposes when boiled, and indium hydroxide separates out: $2InF_3+6H_2O=6HF+2In(OH)_3$. The fluoride is reduced to the metal when heated in a stream of hydrogen. P. C. Chabrié and A. Bouchonnet prepared white needles of **enneahydrated indium trifluoride,** $InF_3.9H_2O$, by the slow evaporation on a water-bath of a soln. of well-washed indium hydroxide in hydrofluoric acid. The crystals fume when exposed to air; they are sparingly soluble in cold water; insoluble in alcohol and ether; and readily soluble in cold hydrochloric acid and hot nitric acid. When indium chloride is treated with an excess of ammonium fluoride, large, colourless, octahedral crystals of an **ammonium fluoindate** separate out, and the reaction has been suggested by A. C. Huysse, and P. Kley as a *microchemical test* for indium.

C. Winkler,[2] and L. F. Nilson and O. Pettersson prepared **indium trichloride,** $InCl_3$, by passing a current of chlorine over the heated lower chlorides; F. Reich and F. Richter, by passing chlorine over the heated oxide, or better, an intimate mixture of the oxide and carbon. The product was purified by redistillation in a stream of carbon dioxide. A. Thiel prepared the trichloride by the action of moist hydrogen chloride on the metal between 120° and 320°. Indium trichloride forms white lustrous plates. A. Thiel found the sp. gr. of the solid to be 4·0. Indium trichloride does not volatilize appreciably below 440°, but readily volatilizes at about 600°. W. Odling noted that vaporization begins at a dark red heat. W. Hampe said that this chloride melts readily to a pale yellow liquid which boils at a rather higher temp. Vapour density determinations by H. Biltz, V. and C. Meyer, and by L. F. Nilson and O. Pettersson show that between 600° and 850°, the mol. wt. agrees with the formula $InCl_3$, but at a higher temp., 1100°–1200°, the vapour density falls from the theoretical value 7·58 (air unity) for $InCl_3$, to 6·23, indicating that the trichloride is dissociating, probably forming a lower chloride. W. Hampe said that the electrical conductivity at the m.p. is small, but much greater at the b.p. The trichloride is very deliquescent, and C. Winkler found that it readily dissolves in water with a loud hissing noise, and the development of much heat. The aq. soln. was found by A. Thiel to be slightly hydrolyzed, but not much hydrogen chloride is lost when the aq. soln. is evaporated at 100°, but F. Reich and T. Richter obtained an insoluble **indium oxychloride** as a residue when the aq. soln. is evaporated at a high temp. A. Thiel made the oxychloride InOCl, as a white powder, very sparingly soluble in water, by the action of chlorine mixed with oxygen on indium dichloride. C. Winkler did not confirm this observation. The aq. soln. is very difficult to crystallize, the eq. conductivity of aq. soln. with three gram-eq. per litre is 10·2; with 0·003 gram-eq., 101; and with 0·0003 gram-eq., 225. A. Thiel also gave the potential of the normal electrode (−0·620 volt) against *N*-soln. as 0·094 volt; against 0·1*N*-soln., 0·108 volt; and against 0·01*N*-soln., 0·119 volt. C. Willgerodt found indium trichloride acted as a catalytic agent in chlorinating benzene.

L. M. Dennis and W. C. Geer found that when indium trichloride is vaporized in a stream of dry ammonia, a volatile white crystalline addition product, **indium amminochloride,** is formed; and R. E. Meyer dissolved indium sesquioxide in a soln. of ammonium chloride in hydrochloric acid, conc. the soln. by evaporation;

on cooling, small lustrous colourless crystals of, presumably, **ammonium tetrachloroindate,** $NH_4InCl_4.\frac{1}{2}H_2O$, were obtained. The crystals were readily soluble in water, but were not hygroscopic. R. C. Wallace obtained rhombic bipyramidal crystals of **monohydrated ammonium pentachloroindate,** $(NH_4)_2InCl_5.H_2O$, with axial ratios $a:b:c=0·9668:1:1·4005$, and sp. gr. 2·281 at 20°. R. E. Meyer similarly prepared deliquescent needles of **lithium hexachloroindate**—presumably $Li_3InCl_6.nH_2O$ in a similar manner. By a similar process, too, R. E. Meyer prepared crystals of **dihydrated potassium hexachloroindate,** $K_3InCl_6.1\frac{1}{2}H_2O$, or better, according to R. C. Wallace, $K_3InCl_6.2H_2O$, in white transparent tetragonal bipyramids to which A. Fock assigns the axial ratio $a:c=1:0·8187$, and R. C. Wallace, the sp. gr. 2·483 at 20°; the crystals have a feebly negative double refraction, and are isomorphous with the corresponding dihydrated hexabromoindate. They are easily soluble in water; and they always contain an excess of potassium chloride which crystallizes along with the indium salt. P. Kley said that the crystals are sparingly soluble in hydrochloric acid. P. Kley prepared **rubidium hexachloroindate**, $3RbCl.InCl_3$, from a soln. of indium hydroxide in conc. hydrochloric acid, by adding rubidium chloride; the colourless octahedra are formed so readily that the reaction is recommended as a microchemical test for indium. R. C. Wallace prepared rhombic bipyramids of **monohydrated rubidium pentachloroindate,** $Rb_2InCl_5.H_2O$, have the axial ratios $a:b:c=0·9725:1:1·4084$, and sp. gr. 3·089 at 20°. Isomorphous crystals of **monohydrated cæsium pentachloroindate,** $Cs_2InCl_5.H_2O$, with axial ratios $a:b:c=0·9841:1:1·4033$, and sp. gr. 3·350 at 20°. These crystals are isomorphous with the corresponding ammonium salt, with the corresponding chloro- and bromo-indates and thallates, and with potassium and ammonium chloroferrates—$K_2FeCl_5.H_2O$ and $(NH_4)_2FeCl_5.H_2O$. **Cæsium hexachloroindate**, $3CsCl.InCl_3$, is formed in a similar manner to rubidium hexachloroindate, and the reaction is even more sensitive. E. H. Ducloux recommended this as a *microchemical test* for indium.

L. de Boisbaudran, and A. Thiel prepared colourless crystals of **indium dichloride,** $InCl_2$, by heating the metal in a stream of dry hydrogen chloride; the amber-yellow liquid so formed solidifies to a white crystalline mass. L. F. Nilson and O. Pettersson's value for the vapour density at 958° corresponds with the partial dissociation of the more complex molecule $In_2Cl_4 \rightleftharpoons 2InCl_2$, the dissociation is complete between 1300° and 1400°. According to A. Thiel, indium dichloride in contact with water decomposes into metallic indium and the trichloride with the intermediate formation of indium monochloride. L. F. Nilson and O. Pettersson say that indium reduces indium dichloride to **indium monochloride,** InCl, when the mixture is distilled in a stream of carbon dioxide. The dark red solid melts to a blood-red liquid. The vapour density between 1100° and 1400° corresponds with the simple formula InCl. Water decomposes indium monochloride into indium trichloride and metallic indium. C. Winkler suggested that the dark-brown mass which is formed when chlorine is passed over warm indium, just before clouds of the trichloride appear, is possibly indium subchloride.

The action of bromine on indium is analogous with that of chlorine, and three indium bromides have been reported—InBr, $InBr_2$, and $InBr_3$—together with **indium oxybromide,** stated by R. E. Meyer[3] to be formed as an amorphous non-volatile solid by the action of bromine vapour on heated indium sesquioxide. The oxybromide is stated to be very resistant towards boiling acids and alkalies; but A. Thiel questions whether such a salt really exists. A. Thiel prepared **indium monobromide,** InBr, by passing bromine over warm indium for a short time, and heating the reddish-brown product in a stream of carbon dioxide for about an hour in contact with an excess of the metal. The liquid solidifies to a carmine-red mass which easily sublimes. Hot water decomposes it, forming indium and indium dibromide; it is easily soluble in acids—particularly when these are conc. and hot. The vapour density of indium monobromide at 1130° is 207, that calculated for InBr is 195.

While indium monobromide is the first product of the action of bromine on indium, the further action of bromine on heated indium gives a dark yellow liquid—**indium dibromide,** $InBr_2$—which on solidification furnishes a horn-like mass which is almost without colour. The product can be sublimed in a stream of carbon dioxide. Water converts indium dibromide into a mixture of the tri- and mono-bromides; and, with a more prolonged contact, or when heated, into indium and indium tribromide. It is easily soluble in acids. While the vapour density of indium monobromide at 1330° is nearly normal, that of the dibromide shows that a considerable fraction is dissociated into the monobromide and bromine.

R. E. Meyer, and A. Thiel prepared **indium tribromide,** $InBr_3$, by the action of bromine vapour carried by a current of carbon dioxide over heated indium. The product after many sublimations is colourless or white, and easily volatile. In general properties indium tribromide resembles the trichloride. K. Jauch found the sp. ht. of soln. of N eq. of indium bromide per litre to be:

N	0·5	1·0	2·0	3·0	4 0
Sp. ht.	0·9418	0·8922	0·8020	0·7285	0·6652

A. Heydweiller found for soln. of N gram-eq. of indium tribromide, $InBr_3$, with the eq. wt. 118·19, the sp. gr., D, at 18° with respect to water at the same temp.; the sp. ht., C; the electrical conductivity, K; the eq. conductivity, λ; the refractive index, μ, for the three hydrogen lines; the refraction eq. by the formula $R=M(\mu^2-1)/D(\mu^2+2)$ for sodium light; the refraction eq., R_α, for long waves; and w the eq. rotatory power for sodium light with respect to water at the same temp.:

The mono- and di-halides of indium are unstable in aq. soln. and change into the trihalide and metal. This is symbolized in terms of the ionic hypothesis: $3In' \rightleftharpoons In''' + 2In$; and $3In'' \rightleftharpoons 2In''' + In$. In addition, the salts are appreciably hydrolyzed in aq. soln. Like the cadmium halides, the indium trihalides form complex anions. The abnormally low values for the eq. conductivities of these salts in conc. soln. are taken as evidence of the formation of complex anions. F. Kohlrausch plotted what he called *die lineare Konzentration*, that is, $N^{\frac{1}{3}}$, as a function of the eq. conductivity, as indicated in Fig. 2; these curves emphasize the low values for conc. soln. of cadmium and lithium bromides which form complexes, when contrasted with the normal value for cadmium chlorate which does not form complex ions.

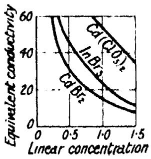

FIG. 2.—Equivalent Conductivity and Linear Concentration of Solutions of Indium and Cadmium Bromides.

R. C. Wallace has prepared a number of complex bromides. The alkali bromoindates of the series, $M_2InBr_5.H_2O$, form rhombic bipyramids—for example, **monohydrated ammonium pentabromoindate,** $(NH_4)_2.InBr_5.H_2O$, has the sp. gr. 3·167 at 20°; the rhombic crystals of **monohydrated rubidium pentabromoindate,** $Rb_2InBr_5.H_2O$, have the axial ratios $a:b:c=0·9803:1:1·3951$, and the sp. gr. 3·409 at 20°; and **monohydrated cæsium pentabromoindate,** $Cs_2InBr_5.H_2O$, the axial ratios 0·9734 : 1 : 1·4180, and the sp. gr. 3·776 at 20°. These salts are isomorphous with the corresponding chloroindates, chlorothallates, and chloroferrates, $(NH_4)_2FeCl_5.H_2O$. There are also tetragonal crystals of **dihydrated potassium hexachloroindate,** $K_3InBr_6.2H_2O$, with a sp. gr. 3·140 at 20°, and isomorphous with the corresponding chloroindates, chlorothallates, and bromothallates.

Iodine unites directly with indium, and much heat is developed. R. E. Meyer, *and* A. Thiel *prepared* **indium triiodide,** InI_3, *by passing iodine vapour, in a stream of carbon dioxide, over heated indium.* R. E. *Meyer said that indium triiodide forms yellow hygroscopic crystals which, at about 199°, readily melt to a reddish-brown liquid which cools to a yellow crystalline mass.* Indium triiodide can be *slowly distilled in a stream* of carbon dioxide at a high temp., but A. Thiel said that the salt dissociates at the high temp. of the distillation, forming iodine and one of the lower indium iodides. Indium triiodide is soluble in a small proportion of water or alcohol, forming a yellowish-brown soln. which, on the addition of more water or alcohol, forms a red emulsion, or a red powder. Chloroform gives a colourless soln.; and xylene, a yellow soln. A. Thiel reported the probable formation of *indium chloroiodide* when indium triiodide is treated with chlorine.

A. Thiel and H. Kölsch[4] measured the f.p. of fused mixtures of indium and iodine, and obtained the curve shown in Fig. 3, where the f.p. of mixtures with one gram-atom of indium are plotted against composition. There is a definite maximum in the curve corresponding with the formation of **indium di-iodide,** InI_2, melting at about 212°. The diiodide has not been definitely isolated since, when the attempt is made to prepare it by fusing together the elements, and distilling the product, the molten iodide dissociates largely into the mono- and tri-iodides: $2InI_2=InI+InI_3$.

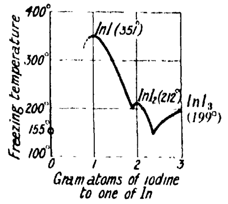

FIG. 3.—Freezing-point Curve of Mixtures of Iodine and Indium.

A. Thiel and H. Kölsch prepared **indium mono-iodide,** InI, by heating iodine with an excess of indium, Fig. 3. Small quantities should be used, or the reaction carried out in an atm. of carbon dioxide. The product is then distilled in an atm. of carbon dioxide at 700°; indium monoiodide is also formed by the repeated distillation of the triiodide in an atm. of hydrogen. The brownish-red solid melts at 351°, and boils at about 700°. It is not decomposed by hot water, but in contact with air, oxidation takes place according to the equation: $2InI+3H_2O+O_2=2In(OH)_2+2HI$. This reaction is slow with cold water, and the hydroxide is obtained in colloidal soln.; with hot water, the hydroxide is in a more granular form easily filtered. Sulphur dioxide converts it into indium sulphide, In_2S_3; and hydrogen sulphide into indium sulphide and indium triiodide. Indium monoiodide dissolves in dilute acids with the evolution of hydrogen; it is insoluble in alcohol, ether, and chloroform.

§ 7. Indium Sulphides

According to C. Winkler,[1] sulphur and indium can be triturated together at 200°, without combining, but union occurs with incandescence at a red heat. A. Thiel made **indium trisulphide,** In_2S_3, by heating indium with an excess of sulphur in a sealed tube at about 500°; and he obtained scarlet-red lustrous crystals by heating indium trioxide in a stream of hydrogen sulphide. According to F. Reich and T. Richter, and R. E. Meyer, indium sulphide is formed when a soln. of an indium salt is treated with potassium monosulphide, K_2S, or a feebly acid soln. with hydrogen sulphide. The precipitation is prevented by mineral acids except when the acidity is very slight; but with acetic acid soln. the precipitation is complete, and much sulphur is at the same time separated. C. Winkler stated that one part of indium dissolved in 30 parts of conc. hydrochloric acid, and diluted with at least 2000 parts of water, is completely precipitated by hydrogen sulphide. He also prepared lustrous yellow crystals of the sulphide by heating an intimate mixture of indium trioxide, sulphur, and sodium carbonate for some time at a red heat, and extracting the soluble matters with hot water. O. Brunck boiled a neutral soln. of an indium salt with sodium thiosulphate and obtained a precipitate of indium sulphide, but in the absence of free acids, the precipitation is not complete. C. Winssinger, and S. E. Linder and H. Picton prepared a **colloidal sol** of indium trisulphide by passing hydrogen sulphide into water in which indium hydroxide is suspended. The golden-yellow sol may be boiled to remove the excess of hydrogen sulphide without flocculation, but the addition of an electrolyte acetic acid, ammonium chloride, and salts generally—coagulates the sulphide.

Indium sulphide appears in yellow or orange plates; in more or less impure brown crystalline masses; and as a yellow colloid. According to C. Winkler, and A. Thiel, the sulphide is not volatile at a red heat, but when roasted in air, it is ultimately converted into the trioxide. Indium sulphide is soluble in conc. mineral acids. F. Hoppe-Seyler used the sulphide for the spectroscopic detection of indium in ores. When the trisulphide is heated to redness in a stream of hydrogen, A. Thiel and H. Kölsch found a dark yellowish-brown sublimate of **indium monosulphide,** In_2S, is produced in minute needle-like crystals. It melts when heated in the absence of air, forming a dark brown liquid, which in air passes into the trisulphide and trioxide. It is readily dissolved by acids, and A. Thiel studied the action of bromine water and hydrogen peroxide. A. Thiel and H. Kölsch prepared a soft reddish-brown mass of **indium disulphide,** In_2S_2, or InS, by heating the metal in a stream of hydrogen sulphide.

According to S. E. Linder and H. Picton, when hydrogen sulphide is passed over indium hydroxide, the colour remains white for ten minutes and then gradually changes to a pale yellow; it is supposed that the white product is normal **indium hydrosulphide,** $In(HS)_3$. A similar white sulphide was obtained by C. Winkler, by treating indium trisulphide with ammonium hydrosulphide. According to F. Reich and T. Richter, a white precipitate is formed when ammonium sulphide is added to an ammoniacal soln. of an indium salt mixed with tartaric acid, or, according to C. Winkler, to a neutral soln. of an indium salt. The last-named also made it by passing hydrogen sulphide into a soln. obtained by adding an excess of ammonium carbonate to an indium salt; or by cooling a boiling soln. of indium sulphide in ammonium polysulphide. R. E. Meyer made it by treating a soln. of an indium salt with potassium hydrosulphide. When washed and dried, it gives off hydrogen sulphide and becomes yellow. The first action of acids is to change it to the yellow sulphide, before it dissolves. It is possible that the white precipitate produced by the alkali sulphide is a hydrated alkali indium sulphide; and that with ammonium sulphide, a hydrated ammonium indium sulphide. R. Schneider obtained **potassium sulphoindate,** $KInS_2$, or $K_2S.In_2S_3$, by melting together indium trioxide, potassium carbonate, and sulphur in the proportions 1 : 6 : 6, and extracting the mass with water. The insoluble, hyacinth-red, quadratic plates were stable in air. The salt is partly oxidized when heated in air; it is not reduced by hydrogen at a red heat; it is decomposed by acids; and it is coloured brown by a soln. of silver nitrate owing to the formation of **silver sulphoindate,** $AgInS_2$. By substituting sodium carbonate for potassium carbonate in the process just described and extracting the mass with cold water, a soln. is obtained which slowly deposits dihydrated **sodium sulphoindate,** $NaInS_2.H_2O$, or $Na_2S.In_2S_3.2H_2O$.

§ 8. Indium Sulphates

The soln. obtained by dissolving indium oxide, hydroxide, or carbonate in sulphuric acid can be evaporated to a thick syrup without crystallization. R. E. Meyer[1] found that if the acid-liquor is allowed to stand in a desiccator for a long time a deliquescent crystalline mass of hydrated **indium hydrosulphate,** $In_2(SO_4)_3.H_2SO_4.8H_2O$, or $InH(SO_4)_2.4H_2O$, is produced. According to C. Winkler, if the acid soln. be heated so as to remove the excess of acid, a gum-like mass is obtained, which, when dried at 100°, has a composition corresponding with enneahydrated **indium sulphate,** $In_2(SO_4)_3.9H_2O$; while if the acid soln. be evaporated to dryness, a white powder is obtained which appears to be a basic sulphate. According to A. Thiel, the hydrated salt intumesces when gradually heated to 250°–300°, and forms a white froth. F. Reich and T. Richter, and C. Winkler obtained small, white, opaque crystals of indium sulphate by concentrating an acid soln. According to L. F. Nilson and O. Pettersson, the sp. gr. is 3 438; and the sp. ht. 0·129 between 0° and 100°. A. Ditte gave 49·039 Cals. as the heat of formation by the dissolution of a gram-eq. of indium in sulphuric acid, and for $In_2O_3+3H_2SO_{4aq.}=In_2(SO_4)_{3aq.}+3H_2O+72·78$ Cals.

A number of complex indium sulphates has been prepared. The ammonium, rubidium, and cæsium indium alums have been reported; F. Reich and T. Richter, H. Rössler, and R. E. Meyer failed to make the lithium, sodium, and potassium indium alums. H. Rössler prepared *ammonium indium alum*, or dodecahydrated **ammonium disulphatoindate,** $(NH_4)_2SO_4.In_2(SO_4)_3.24H_2O$, or $NH_4In(SO_4)_2.12H_2O$, by slow crystallization from a conc. soln. of the constituent sulphates. *Rubidium indium alum*, or dodecahydrated **rubidium disulphatoindate,** $RbIn(SO_4)_2.12H_2O$; and *cæsium indium alum* or dodecahydrated **cæsium disulphatoindate,** $CsIn(SO_4)_2.12H_2O$, were prepared by P. C. Chabrié and E. Rengade in a similar manner. The crystals are regular octahedrons. The crystals of the ammonium salt have no inclination to effloresce in air, but those of the rubidium and cæsium salts do so. C. Soret gave 2·011 for the sp. gr. of the ammonium indium alum; 2·065 for the rubidium salt; and 2·241 for the cæsium salt. The m.p. of the rubidium salt is 42° (J. Locke); and that of the ammonium salt 36°, according to H. Rössler, and 37°–38°, according to C. Soret. H. Rössler found that the m.p. of the ammonium salt is also a transition temp., $NH_4In(SO_4)_2.12H_2O \rightleftharpoons NH_4In(SO_4)_2.4H_2O+8H_2O$; the resulting **tetrahydrated ammonium disulphatoindate** is also obtained by crystallization from a soln. of the alum at 36°. C. Soret found the indices of refraction, μ, of these three alums between 17° and 21° to be:

		G-	F-	b-	E-	D-	C-	B-	a-line
λ		4310	4860	5170	5270	5890	6560	6860	7180
μ	NH_4	1·47750	1·47234	1·47015	1·46953	1·46636	1·46352	1·46259	1·46193
	Rb	1·47402	1·46955	1·46751	1·46694	1·46381	1·46126	1·46024	1·45942
	Cs	1·47562	1·47105	1·46897	1·46842	1·46522	1·46283	1·46170	1·46091

The solubility of indium ammonium sulphate in grams of salt per 100 grms. of water was given by H. Rössler as about 200 at 16° and about 400 at 30° ; P. C. Chabrié and E. Rengade gave for the rubidium salt 44·28 at 15° ; and for the cæsium salt, 3·04 at 16·5°, and J. Locke gave 11·73 at 25°. H. Rössler, and P. C. Chabrié and E. Rengade found that the aq. soln. have an acid reaction owing to hydrolysis, and when heated, they become turbid owing to the separation of basic sulphates, and in the case of the cæsium salt, indium hydroxide. H. Rössler said that the ammonium salt is insoluble in alcohol.

Salts analogous to tetrahydrated ammonium disulphatoindate—*vide supra*—were prepared by H. Rössler when he attempted to make the sodium and potassium indium alums. The aq. soln. of H. Rössler's tetrahydrated **sodium disulphatoindate,** $NaIn(SO_4)_2.4H_2O$, or $Na_2SO_4.In_2(SO_4)_3.8H_2O$, and tetrahydrated **potassium disulphatoindate,** $KIn(SO_4)_2.4H_2O$, or $K_2SO_4.In_2(SO_4)_3.8H_2O$, became turbid when boiled. With the potassium salt, H. Rössler obtained the basic salt : $KIn(SO_4)_2.2In(OH)_3$, **potassium hexahydroxydisulphatoindate.**

§ 9. Indium Carbonate, Nitrate, and Phosphate

According to F. Reich and T. Richter,[1] white crystalline **indium carbonate** is precipitated from a soln. of an indium salt by the addition of an alkali carbonate. When calcined, the oxide is formed. According to C. Winkler, the carbonate is insoluble in soln. of potassium or sodium carbonate, but soluble in one of ammonium carbonate ; when this soln. is boiled the carbonate is again precipitated.

A soln. of indium nitrate is formed by the action of nitric acid on indium oxide, hydroxide, or carbonate ; the neutral soln. crystallizes with great difficulty, and when evaporated in a desiccator, it forms a syrupy liquid from which thin deliquescent plates of trihydrated **indium nitrate,** $In(NO_3)_3.3H_2O$, can be obtained ; the acid soln. furnishes groups of acicular or columnar crystals. A mol of the salt loses two mols of water at 100° ; at a higher temp., nitric acid is given off and a basic nitrate is produced ; and at a still higher temp., the oxide is produced. The retention of occluded gases by the calcined nitrate is discussed in connection with the oxide. L. M. Dennis and W. C. Geer prepared white ammonium nitratoindate, by crystallization from a mixed soln. of ammonium and indium nitrates.

C. Winkler found that indium salt soln. give a white precipitate with soln. of sodium hydrophosphate. The soln. of **indium phosphate** in potash-lye soon becomes turbid.

CHAPTER XXXVI

THALLIUM

§ 1. The History and Occurrence of Thallium

At the beginning of 1861, W. Crookes[1] extracted selenium from the seleniferous deposit of a sulphuric acid factory at Tilkerode in the Harz. The residue remaining after distillation was supposed to contain tellurium, but, when examined spectroscopically, a bright green line was observed; this was attributed to the presence of a new element which was named **thallium,** "from the Greek θαλλός, or Latin *thallus*, a budding twig—a word which is frequently employed to express the beautiful green tint of young vegetation; and which I have chosen because the green line which it communicates to the spectrum recalls with peculiar vividness the fresh colour of vegetation in spring." This discovery was announced in a paper on March 30, 1861: *On the existence of a new element, probably of the sulphur group.* About a year later, A. Lamy observed the green spectral line from the chamber deposit of the sulphuric acid works at Loos where Belgian pyrites were roasted. He established the metallic nature of thallium, and on May 16, 1862, he described the chemical and physical properties of *le nouveau métal.* He showed that thallium forms at least two series of compounds, and that one series of compounds closely resembles the analogous compounds of the alkali metals, and the other, those of lead. Soon afterwards numerous investigations were made on the properties of thallium and its compounds. There has been some discussion of the priority of the discovery of thallium. W. Crookes at first regarded thallium as a homologue of selenium; but A. Lamy recognized its metallic nature and its relations with lead, and with the alkali metals. A. Lamy consequently claimed, as G. Urbain puts it, that thallium did not belong to the tellurium group; that the reactions cited by W. Crookes were illusory; that the green line emanated from an impurity in the materials; and that he himself, not W. Crookes, was the discoverer of thallium. The weighing of the evidence on both sides, shows that W. Crookes is to be regarded as the discoverer of this element; and that the green spectral line is a veritable characteristic of this element. H. L. Wells and S. L. Penfield raised the question whether thallium is a mixture of the two alkali metals with at. wts. 170 and 220 which are missing in the periodic table; but the results of their experiments were nugatory. No element other than thallium could be obtained by the fractional crystallization of the nitrate. V. Meyer has also discussed the elementary nature of thallium. M. Doan has compiled a bibliography of the literature on this element.

Thallium does not occur free. J. H. L. Vogt[2] estimated the ten-mile crust, the hydrosphere, and lithosphere of the earth contained 0·00000000x per cent. of thallium; and F. W. Clarke and H. S. Washington, 0·0000000x per cent. According to H. A. Rowland, the solar spectrum shows no sign of the presence of thallium. The element is an essential constituent of some very scarce minerals which W. Vernadsky said are always of a secondary character and appear to have been formed by the weathering or decomposition of selenium or sulphur compounds. In these minerals, thallium seems to be isomorphically associated with the alkali many aluminosilicates, sulphates, and chlorides; and with silver or lead and sulphides. A. E. Nordenskjöld found the non-crystalline mineral *crookesite* from Skrikerum (Sweden) has a composition approximating $(Cu, Tl, Ag)_2Se$ with 16·27 to 18·55 per cent. of thallium; J. A. Krenner and J. Loczka, and V. M. Goldschmidt found *lorandite*, $TlAsS_2$, from Allchar (Macedonia) had 59·51 per cent. of thallium. It was associated with realgar, and the monoclinic crystals had the axial ratios $a : b : c = 1·3291 : 1 : 1·0780$, and $\beta = 52^\circ\ 71'$. R. H. Solly, and G. F. H. Smith found *hutchinsonite* in the dolomite of Lengenbach (Binnental) is a sulphoarsenide of thallium, lead, silver, and copper approximating $(Tl, Ag, Cu)_2S.PbS.2As_2S_3$, with about 20 per cent. of arsenic; and B. Jezek, and F. Krehlik found that the composition of *urbaite*, from Allchar (Macedonia), approximates $TlAs_2SbS_5$, with 29–30 per cent. of thallium. It occurs in small, deep red, translucent, rhombic crystals with axial ratios $a : b : c = 0·5659 : 1 : 0·4836$.

W. N. Hartley and H. Ramage found spectroscopic indications of thallium in many rocks, and it occurs in a number of minerals as a secondary constituent. Thus, W. Crookes found it in many cupriferous pyrites; W. Vernadsky, in pyrites and marcasite; A. Lamy, in pyrites from Theux, Namur, Phillipeville, Alais, Nantes, Spain, and Bolivia; E. Carstanjen, in pyrites from Meggen; J. W. Gunning, in pyrites from Ruhrort; J. Antipoff, in pyrites from Poland to the extent of 0·3 to 0·5 per cent. thallium; L. Marquardt, in pyrites from Altenhuden; and L. J. Igelström, in the hematite (iron glance) of Sjogrube (Orebro). A. R. von Schrötter found up to 0·006 per cent. of thallium in the lepidolite of Mähren, and in the mica of Zinnwald. C. F. Schönbein also found thallium in lepidolite; W. Vernadsky, also, in lepidolite from Lipowka, in muscovite from Mursinka, zinnwaldite (lithia-mica) from Zinnwald, and Onon; and orthoclase from Mursinka. F. L. Bartlett found thallium in the zinc blende of Leadville, and F. von Kobell in the zinc blende of Geroldseck (Breisgau); F. Exner and E. Haschek, in Cornish pitchblende; E. Linnemann, in the orthite of Arendal; A. de Gramont, in berzelinite, Cu_2Se, and in frenzelite, Bi_2Se_3; F. Bischoff found one per cent. of thallium, and T. L. Phipson, 0·01 per cent. of thallous oxide in samples of pyrolusite; W. Vernadsky, in manganite; W. T. Röppler, in pyritiferous anthracite; O. Vogel, in pitchblende from Johanngeorgenstadt; W. Vernadsky, in some uranium and platinum ores. L. Palmieri found thallium and lithium in the sublimation products of a crater of Vesuvius, and A. Cossa found thallium in the breccia of the lava in the island of Valkano. J. Schramm reported thallium and rubidium, but no cæsium in the carnallite of Kalusz (Galica), thallium only in the sylvine, and none of these three elements in the kainite. F. Hammersbacher found thallium in the carnallite of Stassfurt, but more in the sylvine. A. Cossa found traces of thallium in the potash alum of the Island of Volkano. R. Böttger found thallium, rubidium, and cæsium in the mineral waters of Nauheim, Orb, and Dürrenberg; E. Ludwig and J. Mauthner found thallium in the waters of Carlsbad; and G. J. Mulder, in those of Java.

Thallium also occurs in products derived from thalliferous ores. For instance, W. Crookes found it in the lead chamber deposits of Tilkerode; A. Lamy, in those of Loos; and R. Böttger, in those of Oker, where it is derived from the roastings of the pyrites. F. Wöhler found thallium in the flue-dust of furnaces roasting thalliferous pyrites at Theux (0·5–0·75 per cent. thallium), and at Ringenkuhl; E. Carstanjen, at Meggen (3·5 per cent. thallium); J. W. Gunning, at Ruhrort (1 per cent. thallous chloride); D. Playfair, and others have made similar observations. W. Crookes found 0·29 per cent. of thallium in the raw sulphur obtained from Spanish pyrites, and in the sulphur of Lipari; R. Böttger found thallium in sulphuric acid, and W. Crookes in the hydrochloric acid derived from thalliferous sulphuric acid. R. Bunsen obtained 0·05 per cent. of thallous chloride from the zinc sulphate lye of Goslar which was obtained from Rammelsberg ore. A. Streng found thallium in zinc and cadmium obtained from thalliferous zinc ores—B. Kosmann found 1·4 per cent. of thallium in a sample of zinc. H. N. Warren reported thallium in platinum; W. B. Herapath, and W. P. Jorissen and J. A. Vollgraff, in bismuth; G. Werther, in tellurium; W. Crookes, in cadmium sulphide; and O. Zimmermann, in uranyl hydroxide.

R. Böttger found thallium widely diffused in the vegetable kingdom, for he found it in wine, chicory, tobacco, beet root, beech wood, etc.

A. Holmes and R. W. Lawson have discussed the possibility of thallium or isotopes of thallium being end-products of the radioactive decay of actinium and of thorium.

§ 2. The Extraction of Thallium

The thallium minerals are so very scarce that they are not used as sources of the metal. W. Crookes[1] described processes for the extraction of thallium from some Belgian and Spanish pyrites, but the methods are not employed because it is so much easier to extract thallium from the mud of the lead chambers, and the flue-dust of sulphuric acid works burning thalliferous pyrites. The flue-dust is a kind of concentrate of the thallium in the pyrites. G. Sisson and J. E. Edmondson found the dust collected between the pyrites kiln and the Glover's Tower of a sulphuric acid works contained 0·25 per cent. of thallium, representing one part of thallium per million parts of pyrites burnt. The metal is also extracted from the mother liquors after the separation of zinc sulphate. The general methods are based on the sparing solubility of thallous chloride or iodide ; on the ready formation of a thallium alum which can be easily purified ; on the formation of a sulphide sparingly soluble in alkaline soln., and on the non-precipitability of thallous salts by sodium carbonate.

A. Lamy obtained thallium from the mud of the lead chamber of a sulphuric acid works by first neutralizing the mass with lead oxide or lime; extracting the product 3-5 times with hot water; concentrating the soln. to about one-tenth its volume; precipitating thallous chloride by adding hydrochloric acid; washing with dil. hydrochloric acid; and decomposing the product with hot sulphuric acid. The thallous hydrosulphate was dissolved in water, and freed from lead, silver, and mercury by hydrogen sulphide. The filtrate was conc. by evaporation, and the thallium precipitated by adding zinc, or by electrolysis.

R. Böttger boiled the mud with 4-6 times its weight of water; made the soln. alkaline with sodium carbonate; and boiled the liquid. The soln. was filtered from the black precipitate, mixed with potassium cyanide, boiled, filtered, and treated with hydrogen sulphide. The thallous sulphide so obtained was boiled several times with a conc. soln. of oxalic acid; the filtrate was neutralized with sodium carbonate and the treatment with potassium cyanide and hydrogen sulphide repeated. The thallous sulphide was dissolved in nitric acid of sp. gr. 1·2, evaporated with conc. sulphuric acid, and a cold soln. of the resulting sulphate was treated with zinc to precipitate the thallium.

W. Crookes obtained thallium from flue-dust by a process somewhat analogous to that employed by A. Lamy for chamber-mud. The dust is boiled with dil. sulphuric acid, and the thallium precipitated from the filtered and conc. soln. by the addition of zinc. R. Böttger mixed the neutralized soln. of the flue-dust with sodium thiosulphate; passed in hydrogen sulphide to precipitate the thallous sulphide; and treated the product with nitric acid, etc., as indicated above. F. Wöhler precipitated thallous chloride from the sulphuric acid soln., by adding a soluble chloride. The thallous chloride was converted into sulphate and the soln. electrolyzed. F. Wöhler fused the electrodeposited metal with potassium cyanide out of contact with air. E. Carstanjen used a similar process, but precipitated the thallium with zinc. R. Nietzki, and M. Schaffner precipitated thallous iodide from the aq. extract from the flue-dust; converted the iodide to sulphide by sodium sulphide; and the sulphide to sulphate by sulphuric acid. The thallium was precipitated by zinc or by electrolysis, and the metal fused in a stream of hydrogen or in contact with oxalic acid.

J. W. Gunning, J. Krause, F. Stolba, and F. Förster have also described processes for extracting thallium from the flue-dust; and A. R. von Schrötter, a process for the extraction of thallium from lepidolite and mica. R. Bunsen treated with zinc the mother liquor from the zinc sulphate crystallization vats. The deposit was extracted with dil. sulphuric acid to dissolve the cadmium and thallium; and the thallous iodide precipitated from the soln. by the addition of potassium iodide.

W. Crookes, and A. Lamy found thallium oxide is reduced by hydrogen with difficulty; A. Lamy obtained thallium by treating the carbonate with carbon; by fusing the chloride with zinc; or by heating the chloride with potassium or sodium; G. Werther reduced the iodide by fusion with potassium cyanide; and J. E. Willm obtained thallium by heating the oxalate.

W. Crookes purified thallium or thallous chloride by converting it into sulphate. The slightly acid soln. was treated with hydrogen sulphide to remove traces of mercury, silver, arsenic, antimony, and bismuth; the filtered soln. was treated with aq. ammonia to remove traces of iron and aluminium. The filtrate was conc. by evaporation until crystals of thallous sulphate separated out. Thallium is best obtained from the soln. of thallous sulphate by electrolysis. The electrodeposition of thallium has been discussed by L. Schucht, G. Neumann, W. J. Müller, F. Förster, M. Bose, M. E. Heiberg, G. W. Morden, etc. A. S. Cushman, and F. Ephraim and P. Barteczko used a somewhat analogous process. T. W. Richards and C. P. Smyth thus describe the preparation of purified thallium:

Nuggets of crude metal, containing perhaps 7 per cent. of lead and small amounts of other impurities, were dissolved in dil. pure sulphuric acid. Most of the lead remained undissolved, partly as a metallic powder and partly as precipitated sulphate. The cooled and somewhat dil. soln. was filtered; to it was added dil. redistilled hydrochloric acid drop by drop, with constant stirring. Very little, if any, lead was found in the precipitated thallous chloride, which was washed several times by decantation. Pure conc. redistilled sulphuric acid converted the solid thallous chloride into sulphate. This thallium sulphate, which on dilution gave no precipitate of lead sulphate, was crystallized by cooling to 0°. The long needles of the salt were thoroughly dried, recrystallized at least twice (sometimes thrice) in a silica dish, by cooling with ice a soln. almost saturated at the b.p. The solubility curve is steep and the process efficient. From this sulphate, which must have been amply pure enough for our purpose, metallic thallium was prepared by the electrolysis of the sat. soln. of the sulphate in water; the electrodes were short platinum wires exposing not more than 1 cm. of their length to the soln. The anode was placed on the bottom of the beaker containing the soln. (being protected above by a long glass tube into which it was sealed), while the cathode merely dipped beneath the surface. The heavy red-brown deposit of peroxide at the anode remained at the bottom of the beaker and therefore did not contaminate the crystalline spongy mass of thallium deposited on the cathode above. A current of about 1 amp. was used and the thallium was removed at frequent intervals from the cathode by means of a small glass fork, and it was rinsed thoroughly with pure water, pressed together, and kept under pure boiled water until fused.

G. Bredig and F. Haber[2] prepared **colloidal thallium** by the electrolysis of a soln. of potash-lye (1 : 20) with a thallium cathode. T. Svedberg obtained organosols in ether by his electrical disintegration process. S. Bodforss and P. Frölich found T. Svedberg's method gave good results for colloidal thallium.

§ 3. The Physical Properties of Thallium

According to W. Crookes,[1] the **colour** of thallium is white with a bluish-grey tinge, somewhat paler than lead. A freshly-cut surface has a bright metallic lustre which soon dulls on exposure to air. The **crystal constants** of thallium have not been determined. K. Becker and F. Ebert found that the **X-radiogram** corresponds with a face-centred tetragonal lattice, with a=4·75 A., and c=5·40 A. S. Nishikawa and G. Asahara studied the effect of annealing and rolling on the X-radiogram and showed that there is an abrupt change in the pattern at about 227°. W. L. Bragg estimates the **atomic radius** to be 2·25 A., and M. N. Saha estimated 0·99 A. Thallium precipitated by zinc or by electrolysis appears in needles or plates; a bar of the metal is crystalline and when bent emits a sound like the "cry of tin." According to A. Lamy, the **specific gravity** of thallium is 11·862; G. Werther gave 11·777–11·900; L. de la Rive gave 11·808 for wire at 11°, and 11·858 at 11° for the cast metal; W. Crookes gave 11·91 for wire, 11·88 for the pressed metal, and 11·81 for the cast metal. T. W. Richards and J. H. Wilson gave 11·85 for the sp. gr. of thallium at 20°. D. Omodei gave 11·509 for the sp. gr. of thallium at the m.p.; and H. Endo, 11·7270. The latter found thallium gives a 3·23 per cent. expansion during solidification; D. Omodei gave 4·3 per cent.; and M. Töpler, 3·1 per cent. W. Crookes, and A. Lamy found that the metal is soft enough to be scratched by the finger-nail, and to be cut with a knife; it is scratched by lead. According to J. R. Rydberg, the **hardness** of thallium is 1·2 when that of lead is 1·5. C. A. Edwards gave 6·95 for the hardness of thallium when that of tin is 15·6, and copper, 53. P. Nicolardof showed that thallium is hardened by hammering. C. A. Edwards and M. A. Herbert gave 3·2 for the **plasticity** number when that of copper is 49·3. J. H. Hildebrand and co-workers computed the **internal pressure**. The **malleability** of thallium is high, and the tenacity low. A. Lamy found it could be rolled into plates 0·015 mm. thick. According to W. C. Roberts-Austen, thallium with 0·193 per cent. of impurity has a **tensile strength** of 6·21 tons per sq. in., and an elongation of 8·6 per cent. on 3 ins. H. von Wartenberg found that thallium can dissolve some oxygen, presumably as thallous oxide, and retain its ductility. Thallium with 0·5 per cent. of oxygen can be drawn like thallium alone into short wires, but if 1·3 per cent. of oxygen is present, it loses this property. T. W. Richards and co-workers found the **compressibility** of thallium, *i.e.* the average fractional change of volume between 100 and 500 megabars press., to be $2·3 \times 10^{-6}$ per megabar, at 20°; P. W. Bridgman gave $3·4 \times 10^{-6}$ at 30°, and $3·67 \times 10^{-6}$ at 75°, and he found that if v denotes the vol. at $\theta°$ and atm. press., and δv, the change in vol. by the application of a press. p kgrms. per sq. cm., then:

p . . .	3000	6000	9000	12,000
$\delta v/v \times 10^7$ at 30° .	−0·00978	−0·01872	−0·02700	−0·03505
$\delta v/v \times 10^7$ at 75° .	−0·01011	−0·01908	−0·02724	−0·03554

and $-(da/adp)=1·53 \times 10^{-5}$ for extruded thallium, where a denotes the coeff. of linear expansion. N. Werigin, J. Lewkojeff, and G. Tammann measured the velocity of flow of solid thallium at different temp. under high press., and found evidence of a transformation at about 187°. N. S. Kurnakoff and S. F. Schemschuschny found the flowing press. to be 5·8 kgrms. per sq. mm.

M. Levin found that thallium exists in two allotropic forms which are enantiotropic $\alpha\text{-Tl} \rightleftharpoons \beta\text{-Tl}$ with the **transition temperature** at 226°; according to R. S. Williams, the temp. is not affected by the presence of antimony. G. I. Petrenko gave 227° for the transition temp.; M. Chikashigé, 231·8°; N. S. Kurnakoff and N. A. Puschin, 227°; K. Lewkonja, 230·5°; L. Densky, 224°; G. Voss, 238°; M. Werner, 226°; T. W. Richards and C. P. Smyth, 235·3°; N. S. Kurnakoff, S. F. Schemtschuschny, and V. Tararin, 229°; P. Pavlovitch, 234°; G. D. Roos, 233°; P. Fuchs, 231°–233°; and S. Nishikawa and G. Asahara, 227°. M. Werner studied the effect of press. up to 3000 kgrms. per sq. cm. on the transition temp., and found the slope at the transition temp. is only −2° per 1000 kgrms.; so that the transition temp. falls from 226° for $p=1$ kgrm. per sq. cm., to 220° for $p=3000$ kgrms. per sq. cm. As the temp. passes through 226°, the volume contracts 0·000044 c.c. per gram, and dT/dp is 0·002° per kgrm. P. W. Bridgman sought for a third modification, but none appeared up to 12,000 kgrms. per sq. cm. at 200°.

According to H. Fizeau, the coeff. of **linear expansion** is 0·00003021 at 40°, and 0·0000325 at 50°; and the coeff. of **cubical expansion** of the liquid between 302° and 351° is 0·000150, according to D. Omodei, and 0·000128, according G. Pacher. A gram of thallium expands on melting 0·0027 c.c. or 3·1 per cent., according to M. Töpler, or 3·22 per cent., according to G. Pacher. A. Lamy gave 0·0325 for the **specific heat**; and H. V. Regnault gave 0·0335. H. C. Schmitz found the sp. ht. between −192° and 20° to be 0·0300, and 0·0326 between 20° and 100°;

while P. Nordmeyer and A. L. Bernoulli obtained 0·0379 between −185° and 20°. H. Bürger found

	−80°	−50°	−20°	0°	50°	100°	150°	180°
Sp. ht. . .	0·0288	0·0288	0·0289	0·0291	0·0296	0·0305	0·0316	0·0324
At. ht. . .	5·875	5·876	5·986	5·939	6·058	6·225	6·446	6·609

The sp. ht. dQ/dT at $\theta°$ is represented by $0·028757+0·0_{7}5505(\theta+80)^2$; and between −80° and $\theta°$, and $Q=0·028757(\theta+80)+0·0_{7}1835(\theta+80)^3$. T. W. Richards and F. G. Jackson gave 0·0296 for the mean sp. ht. between −192° and 20° ; and W. Nernst and F. Schwers, gave 0·0277 at −177·3°, and 0·0143 at −250·1°. G. N. Lewis and co-workers, and E. D. Eastman gave 14·6 cals. per degree for the **entropy** of thallium at 25° and atm. press. According to H. C. Schmitz, the at. ht. at −85° is 6·12, and at 60°, 6·65. E. van Aubel discussed the theoretical value of the at. ht. A. Lamy said thallium has a low **thermal conductivity,** while W. Crookes regarded it as a good conductor. W. B. Brown found a drop of about one-tenth in the thermal conductivity of thallium at about 120°, which is supposed to represent a polymorphic change.

A. Lamy gave 290° for the **melting point** of thallium ; W. Crookes, 285° ; D. Omodei, 204·05 ; C. T. Heycock and F. H. Neville, 303·7° ; N. S. Kurnakoff and N. A. Puschin, 301·2°–301·7° ; R. S. Williams, P. Pavlovitch, and M. Chikashigé, 301° ; A. von Vegesack, 302° ; K. Lewkonja, 299·4° ; N. S. Kurnakoff, S. F. Schemtschuschny, and V. Tararin, 301·2° ; P. Fuchs, 301·7° ; T. W. Richards and C. P. Smyth, 303·5° ; H. Endo, and W. R. Mott, 303·7° ; G. D. Roos, 302° ; F. Doerinckel, 311° ; G. I. Petrenko, 303°–304° ; and G. K. Burgess gave 302° ± 1° for the best representative value ; and W. Guertler and M. Pirani, 301°. C. T. Heycock and F. H. Neville gave 301°–302° for the f.p. of thallium, and they also gave 5·12 cals. per gram for the **latent heat of fusion,** while F. W. Robertson gave 7·2 cals. ; T. W. Richards and C. P. Smyth, 8·3 cals. ; G. N. Lewis and M. Randall, 7·1 cals. ; and G. D. Roos, 7·38 cals. per gram. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of sodium, cadmium, tin, lead, and bismuth by thallium. According to W. Crookes, thallium volatilizes at a red heat, boils at a white heat, and it can be distilled in a stream of hydrogen. G. W. A. Kahlbaum, K. Roth, and P. Siedler distilled thallium in vacuo. F. Krafft and A. Knocke found that thallium begins to volatilize at 174° in vacuo, and the **boiling point** is 818° under the press. of its own vapour 150 mm., or at 1462° at 760 mm. press. H. Biltz and V. Meyer gave 1650° nearly ; E. Isaac and G. Tammann gave 1515° for the b.p. under normal press. ; W. R. Mott, 1280° ; G. E. Gibson, 1660° ; and H. von Wartenberg gave for the **vapour pressure** 0·056 mm. at 634° ; 1·329 mm. at 783° ; 24·31 mm. at 970° ; and 760 mm. at 1306° ; and for the latent **heat of vaporization,** 28 Cals. ; G. E. Gibson gave 38 Cals. The **vapour density**—air unity—at 1636° was found by H. Biltz and V. Meyer to be 16·115 ; and 14·248 at 1728° ; H. Biltz gave 14·77 at 1649°. The calculated values for a monatomic mol., Tl, is 14·167 ; H. von Wartenberg obtained a vap. density 220—H unity—between 1320° and 1690°.

The **atomic refraction** or eq. refraction of thallium, according to J. H. Gladstone,[2] is 21·6 with the H_{α}-line ; and, according to W. J. Pope, 22·14 with the D-ray. C. A. Valson has made some observations on this subject. J. C. McLennan gave for the index of refraction, μ, of thallium vapour at 540°, for light of wave-length λ,

λ .	4358·56	4861·49	5460·97	5769·45	5790·49	5893	6234·31	6563·04
μ .	1·000229	1·000110	1·000293	1·000222	1·000144	1·000165	1·000309	1·000142

He also obtained an anomalous dispersion for wave-lengths 5350·65 A., and 6000 A. H. R. von Traubenberg found $23·3\times10^{-4}$ cm. for the range of the **α-rays** from radium-C in thallium. J. Stark and G. von Wendt studied the **Stark effect** with **canal rays.**

The discovery of thallium by W. Crookes was due to its producing a characteristic green spectral line, and this was confirmed by the observations of A. Lamy.

Thallium and its compounds colour the non-luminous gas-flame an intense green, but, as R. Bunsen showed, the coloration does not persist very long on account of the volatility of the thallium salts. The intense green thallium line has the wave length $\lambda=5350{\cdot}7$. Its position is very near the barium band $\lambda=5347{\cdot}0$, the Ba_a of R. Bunsen and G. Kirchhoff: but the two are not liable to be confused because the barium band is broader and less intense than the thallium line. According to A. Perot and C. Fabry, the green thallium line is really a triplet. J. Nicklès said that the presence of sodium chloride prevents the appearance of the green ray, but W. Crookes showed that this is wrong. C. Fredenhagen found that the chlorine flame is not coloured by thallium. F. Kurlbaum and G. Schulze said that the temp. of an alcohol flame coloured by thallous chloride is 1476°, and if coloured by sodium chloride, 1409°. A. Lamy said 0·000002 mgrm. of thallium can be detected from its flame spectrum. W. Schuler, and A. de Gramont also studied the sensitiveness of the spectral lines. The most intense lines in the arc spectrum are 2709·33, 2767·96, 2918·42, 2921·66, 3229·89, 3519·37, 3529·53, 3775·89, 5350·70; and in the spark spectrum, 3519·37, 3529·53, 3775·89, and 5350·70.

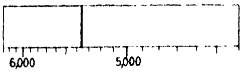

FIG. 1.—Flame Spectrum of Thallium.

The **flame spectrum** has been studied by J. Müller, F. Bernard, E. Ketteler, J. Plücker and W. Hittorf, E. Mascart, R. Rühlmann, A. Cornu, L. de Boisbaudran, A. Gouy, J. N. Lockyer, G. D. Liveing and J. Dewar, A. A. Michelson, D. Cochain, J. M. Eder and E. Valenta, A. Hagenbach and H. Konen, H. Auerbach, C. Fritsch, etc. J. Papish said that thallium chloride dissociates in Bunsen's flame and the free metal colours the flame and may be deposited on a cold surface as a brown mirror; with the hydrogen flame in air, metallic thallium also deposits from the innermost core, but the luminescence of the outer core is probably due to an oxide. The **spark spectrum** has been investigated by W. Huggins, R. Thalén, L. de Boisbaudran, R. Capron, W. N. Hartley and co-workers, E. Demarçay, A. Hagenbach and H. Konen, F. Exner and E. Haschek, J. M. Eder and E. Valenta, J. H. Pollok, etc.; the **arc spectrum,** by J. Tyndall, R. Capron, H. Kayser and C. Runge, H. A. Rowland, A. Hagenbach and H. Konen, F. Exner and E. Haschek, J. M. Eder and E. Valenta, C. E. Gissing, and W. Huppers, B. E. Moore, etc.; the **ultra-violet spectrum,** by W. A. Miller, E. Mascart, G. D. Liveing and J. Dewar, A. Cornu, L. and E. Bloch, F. Exner and E. Haschek, E. Néculcéa, R. W. Wood and D. V. Guthrie, etc.; the **ultra-red spectrum,** by H. Becquerel, E. P. Lewis, F. Paschen, etc.; the **band spectrum,** by J. Plücker and W. Hittorf, H. Konen, W. N. Hartley, etc.; and the **cathode ray spectrum,** by E. P. Lewis. The high frequency or **X-ray spectrum** has been studied by M. Siegbahn and E. Friman, D. Coster, E. Hjalmar, etc. The **absorption spectrum** of the vapour has been examined by J. N. Lockyer and W. C. Roberts-Austen, W. Grotrian, J. C. McLennan and co-workers, J. A. Carroll, etc. Thallium salts give no absorption spectrum. According to J. Formanek, if tincture of alkanna be mixed with an aq. soln. of thallium nitrate, the liquid is not changed, but if a few drops of ammonia are added, the liquid becomes blue, and it shows two absorption bands—one at $\lambda=6288$, and the other at $\lambda=5770$. The nature of the spectral lines, and the **series spectra** of thallium have been discussed by C. Ciamician, G. D. Liveing and J. Dewar, W. Grotrian, A. Fowler, J. A. Carroll, A. Cornu, W. N. Hartley, H. Wilde, J. Barnes, L. Janicki, P. G. Nutting, etc. H. Kayser and C. Runge found two subordinate series of lines:

FIRST SERIES.	SECOND SERIES.
$10^8\lambda^{-1}=41542{\cdot}7-132293n^{-2}-1265223n^{-4}$	$10^8\lambda^{-1}=41506{\cdot}4-122617n^{-2}-790683n^{-4}$
$10^8\lambda^{-1}=49337{\cdot}6-132293n^{-2}-1265223n^{-4}$	$10^8\lambda^{-1}=49301{\cdot}3-122617n^{-2}-790683n^{-4}$

The relationship between the spectra of aluminium, gallium, indium, and thallium has been discussed in connection with the first-named element.

F. L. Mohler, and W. J. Humphreys studied the effect of *pressure* on the thallium lines; R. W. Wood and D. V. Guthrie, and H. Finger, the effect of the *medium*; C. Fievez, the action of a *magnetic field*; A. A. Michelson, the **Zeeman effect**; J. N. Lockyer, and J. Steinhausen, the *enhanced lines*; G. D. Liveing, the differences in the spectra at the anode and cathode; and O. Lummer and E. Pringsheim, and F. Schön, H. Geisler, the *anomalous dispersion*. J. Stark and G. von Wendt [3] found that the compounds of thallium emit characteristic lines when acted upon by **canal rays,** and these have been studied by H. Smith, E. Beckmann and H. Linder, etc. In the **X-ray spectrum** the M-series was measured by W. Duane and co-workers, and M. Siegbahn and E. Jönsen; and the L-series, by D. Coster, M. de Broglie, W. Duane and R. A. Patterson, and M. Siegbahn, who found, in Angström units, or 10^{-8} cm. units, $\alpha_2\alpha'=1{\cdot}21603$; $\alpha_1\alpha=1{\cdot}20471$; $\beta_1\beta=1{\cdot}01266$; $\beta_2\gamma=1{\cdot}00786$; $\gamma_1\delta=0{\cdot}86529$; $\epsilon=1{\cdot}385$; $\eta=1{\cdot}125$; $\gamma_2\theta=0{\cdot}8447$; $\beta_4\upsilon=1{\cdot}0371$; $\beta_3\phi=0{\cdot}9978$; $\gamma_3\chi=0{\cdot}8379$; and $\gamma_4\psi=0{\cdot}8100$. The M-series of the X-ray spectrum was reported by G. Wentzel, and E. Hjalmar, who gave $\alpha_1=5{\cdot}468$; $\alpha'=5{\cdot}461$; $\alpha=5{\cdot}4499$; $\beta_1=5{\cdot}254$; $\beta=5{\cdot}2384$, and $\gamma=4{\cdot}802$. W. Duane and co-workers studied the absorption of X-rays by thallium. M. N. Saha made observations on the **ionizing potential** of thallium vapour; and F. L. Mohler and co-workers found this to be 6·04 volts. F. L. Mohler and A. E. Ruark found for the ionizing potential $2p_2=6{\cdot}082$; and $2p_1=5{\cdot}120$; and for the **resonance potentials,** $2p_2-2p_1=0{\cdot}962$; $2p_2-2s=3{\cdot}269$; and $2p_2-3d_{1,2}=4{\cdot}47$. J. E. P. Wagstaff gave $2{\cdot}6\times10^{12}$ for the **vibration frequency**.

According to W. Crookes,[4] thallium is a good conductor of electricity, but, according to A. Lamy, it is a bad one. Measurements of the **electrical conductivity** have been made by J. R. Benoit, A. Schulze, L. de la Rive, and A. Matthiessen and C. Vogt. J. Dewar and J. A. Fleming's results for solid thallium between −183° and 98·5°, re-calculated by H. Dickson, and G. Vicentini and D. Omodei's value for liquid thallium at 294°, are, in reciprocal ohms (mhos) per cm. cube,

	−83°	−78°	−40°	0°	20°	60°	98·5°	29·4°
Mhos $\times10^{-4}$ . . .	24·5	8·46	6·83	5·68	5·28	4·54	4·05	1·35

The effect of *temperature* on the **electrical resistance,** R, at $\theta°$ between 0° and 100° is represented by A. Matthiessen and C. Vogt as $R=R_0(1+0{\cdot}00402640\theta+0{\cdot}0_58844\theta^2)$, where R_0 represents the value at 0°; J. Dewar and J. A. Fleming gave $R=R_0(1+0{\cdot}003980\theta)$ between 0° and 100°; P. W. Bridgman found $R=R_0(1+0{\cdot}005170\theta)$ between 0° and 100°; and G. Vicentini and D. Omodei, gave $R=R_0(1+0{\cdot}0041080\theta+0{\cdot}0_53016\theta^2+0{\cdot}0_88183\theta^3)$ for the solid between 0° and 294°, and $R=R_0(1+0{\cdot}000350\theta)$ for the liquid between 294° and 350°. M. Werner found an abrupt change in the electrical conductivity of thallium wire at the transition temp. 226°; and the temp. coeff. of the two modifications are different. G. Vicentini and D. Omodei's curve does not show this change. M. Werner gives $R=R_0(1+0{\cdot}0023\theta)$ for the interval 0° to 226°; and $R=R_0(1+0{\cdot}00265\theta)$ for the interval 226° to 302°, the m.p. A. Schulze gave for the sp. resistance of the solid at the m.p., 37×10^{-6}, and of the liquid, 74×10^{-6}. According to C. A. Crommelin, and W. Tuyn and H. K. Onnes, thallium becomes a super-conductor of electricity at 2·3° K. P. W. Bridgman found a discontinuity in the resistance of thallium at a low temp. before the metal becomes super-conducting. The effect of *pressure* was studied by P. W. Bridgman, who found the following relative values for the resistance between 0° and 100°, and between 0 and 1200 kgrms. per sq. cm. press.:

		0°	25°	50°	75°	100°
R . .		1·000	1·1292	1·2585	1·3877	1·5170
Press. Coeff.	0 kgrm. .	$-0{\cdot}0_41310$	$-0{\cdot}0_41358$	$-0{\cdot}0_41393$	$-0{\cdot}0_41425$	$-0{\cdot}0_41456$
	12000 kgrms. .	$-0{\cdot}0_41017$	$-0{\cdot}0_41023$	$-0{\cdot}0_41028$	$-0{\cdot}0_41028$	$-0{\cdot}0_41024$
	average .	$-0{\cdot}0_41151$	$-0{\cdot}0_41165$	$-0{\cdot}0_41183$	$-0{\cdot}0_41203$	$-0{\cdot}0_41226$

A. Stein discussed a relation between the m.p. and the electrical resistance of thallium and other metals. A. T. Waterman studied the electronic theory of the conductivity. W. P. Davey calculated the **atomic radius** of Tl′-ion in thallous chloride to be 1·77 A.

M. Werner measured the **Seebeck effect,** that is, **thermoelectrical force** of the thallium-copper couple. There is a slight discontinuity in the e.m.f., E, at 226°, and he represents the values of E between 0° and 225° by $E=24+0{\cdot}016119(\theta-225)+0{\cdot}00039768(\theta^2-225^2)$; and between 225° and 249°, by $E=24-1{\cdot}0677(\theta-225)+0{\cdot}0026042(\theta^2-225^2)$. W. H. Steele made an observation on the thermoelectric force of the couple at 200°. P. W. Bridgman gave for the thallium-lead couple at atm. press. $10^6E=1{\cdot}659\theta-0{\cdot}00134\theta^2-0{\cdot}0000056\theta^3$ volts; for P, the **Peltier effect,** $10^6P=(1{\cdot}659-0{\cdot}00268\theta-0{\cdot}0000168\theta^2)(\theta+273)$ volts; and for σ, the **Thomson effect,** $10^6\sigma=(-0{\cdot}00268-0{\cdot}0000336\theta)(\theta+273)$ volts per degree. For couples composed of one branch of compressed and one branch of uncompressed thallium, P. W. Bridgman found the thermoelectric force in volts $\times 10^6$ to be for press., p, in kgrms. per sq. cm.:

	10°	20°	40°	60°	80°	100°
p 2,000 . .	+0·88	+1·81	+3·84	+6·07	+8·43	+10·87
6,000 . .	2·47	5·07	10·59	16·48	22·70	29·21
12,000 . .	4·26	8·78	18·53	29·15	40·49	52·46

The e.m.f. is positive and increases regularly with temp. and press. Similarly for the Peltier effect in joules per coulomb $\times 10^6$:

	0°	20°	40°	60°	80°	100°
p 2,000 . .	+23	+28	+33	+38	+42	+46
6,000 . .	66	78	89	101	112	124
12,000 .	112	136	160	183	206	229

The Peltier effect is positive and increases with temp. and press. Likewise also for the Thomson heat effect in joules per coulomb per degree $\times 10^8$:

	0°	20°	40°	60°	80°	100°
p 2,000 . .	+16	+15	+12	+12	+9	+6
6,000 . .	38	32	28	27	26	26
12,000 . .	79	73	67	60	55	50

The Thomson heat effect increases with press. except at the maximum temp. and press., but it decreases regularly with rising temp. J. C. McLennan found the **ionizing potential** for the single line spectrum of thallium vapour to be 2·28 volts—analogous with the corresponding 4·9 volts of mercury vapour; and the value 8·29 volts—analogous with the 10·27 volts of mercury vapour. F. L. Mohler and A. E. Ruark studied the different stages in the excitation of the thallium spectrum. H. Greinacher studied the **flame ionization** by thallium salts. A. Lamy found thallium to be diamagnetic, and K. Honda found the **magnetic susceptibility** at ordinary temp. to be $-2{\cdot}9\times10^{-6}$ vol. units. Observations were also made by S. Meyer, and M. Owen.

B. Neumann [5] found the absolute potential of thallium in N-$TlNO_3$ to be +0·112 volt; in N-Tl_2SO_4, +0·114 volt; and in N-TlCl, 0·151 volt. N. T. M. Wilsmore gave for the sequence of metals in the electrochemical series:

K . . .	Mn	Zn	Cd	Fe	Tl	Co	Ni . . .	H
+3·20 . . .	+1·075	+0·770	+0·420	+0·340	+0·322	+0·232	+0·228 . . .	0

Thallium has therefore a decided tendency to assume the ionic state. J. F. Spencer, R. Abegg, I. Shukoff, and F. J. Brislee made observations on this subject. There is a marked difference between the **potential difference** of thallium and a sat. thallium amalgam. T. W. Richards and C. P. Smyth found that purified compact thallium possesses at 20° an electrode potential 2·1 millivolts higher than sat. thallium amalgam. When immersed in a soln. normal in thallous ions and connected with a normal calomel electrode, the total potential 0·6192 volt is indicated at 25°. The potential of pure thallium is not influenced by quenching the metal, which is so soft that no important strain can exist in it. α-thallium is the only phase of the pure metal stable at room temp. Finely divided electrolytic thallium sponge gives a potential 0·6 millivolt higher than the compact fused form. The difference is probably due to the fine state of division, and disappears on long standing. The difference of potential shown by β-thallium (if it could exist at ordinary temp.) would probably be nearly three times as great. G. Jones and C. W. Schumb measured the potential of the thallium electrode in a sat. soln. of thallous chloride, and the e.m.f. of Tl | $TlCl_{sat.}$, 0·1*N*-KCl | HgCl, with normal and decinormal calomel electrodes at 25° and 0°, and found $E=+0·71821$ volt at 25° and +0·7582 volt at 0°; and with *N*-KCl, $E=+0·7290$ volt at 25° and +0·7102 volt at 0°. This gives for the normal potential of the thallium electrode, +0·5885 volt at 0° and +0·6188 volt at 25°. G. Tammann studied the potential difference of thallium and fused cuprous, silver, stannic, and lead chlorides, and of thallous chloride with magnesium, manganese, or aluminium. R. Kremann and co-workers investigated the e.m.f. of the cell Tl | *N*-Na_2SO_4 | $Tl_{n-1}Na_n$, and similarly with the potassium alloys. G. N. Lewis and C. L. von Ende showed that early measurements gave anomalous results with Nernst's formula for the relation between the thallium potential and the conc. of the thallium ion, because adequate precautions were not taken to prevent the oxidation of the thallium electrode by the oxygen dissolved in the soln. As a consequence, the conc. of the thallous ion next to the electrode is increased, and the percentage change is greater the more dil. the soln. H. G. Denham assumed that metallic thallium in the presence of thallous ions forms sub-thallous ions; F. Kohlrausch and H. von Steinwehr attributed an analogous trend in the conductivity of thallous chloride soln. to the tendency of thallium to form complex ions; and it might also be supposed that a double ion $Tl_2^{\cdot\cdot}$ is formed as in the case of univalent mercury. G. N. Lewis and C. L. von Ende found that if *C* denotes the conc. of the salt in soln.; α, the degree of ionization computed from conductivity measurements; C_1, the ionic conc.; and *E*, the potential against the sat. thallous chloride electrode, then the values of *E* calculated by Nernst's equation show no anomaly in the e.m.f. behaviour of the thallous ion when precautions are taken to prevent electrode oxidation:

	C	α	C_1	*E* (obs.)	*E* (calc.)
$TlNO_3$	0·1000	0·79	0·0790	−0·0422	−0·0438
$TlNO_3$	0·0333	0·88	0·0293	−0·0183	−0·0182
TlCl (sat.) . .	0·0161	0·89	0·0143	0	0
$TlNO_3$	0·0100	0·93	0·0093	+0·0113	+0·0113
TlBr (sat.) . . .	0·00199	0·97	0·00193	+0·0513	+0·0516

The potential of purified thallium against hypothetical normal thallous chloride is 0·6170 volt at 25° when the normal calomel electrode is zero. There is here no evidence supporting H. G. Denham's conclusion that thallium forms sub-thallous $Tl_2^{\cdot}$-ions. T. W. Richards and C. P. Smyth's observations led them to the following conclusion:

> α-thallium dissolves mercury, increasing in hardness and volume up to about 5 per cent. of mercury. When more mercury is added, another solid phase of about the same hardness and volume, but containing more mercury, appears. These two phases appear to exist mixed together in equilibrium, over the range from about 5 per cent. to 10 per cent. of mercury at 20°. With more than about 10 per cent. of mercury, the α-thallium solid soln. ceases to exist and the other phase continues to dissolve mercury in solid soln. until it is saturated (with perhaps 15 per cent. of mercury). The other solid phase is probably a solid soln. of mercury in β-thallium, which appears in definite crystalline form, making the amalgam friable after the admixture of an α-thallium has been eliminated. β-thallium can exist at ordinary temp. only in the presence of much mercury, but it is always the form present in equilibrium with the liquid amalgam.

According to L. Jonas, when a soln. of thallous hydroxide is electrolyzed, thallium is deposited on the cathode and an oxide on the anode. The oxide contains slightly less oxygen than is required by the formula Tl_2O_3, its composition being better represented by $17Tl_2O_3$, Tl_2O. The quantity deposited is equal to that calculated by means of Faraday's law. The process is reversed when the direction of the current is reversed. The chemical reaction in the cell Tl_2O_3 | Tl·OH′ | Tl is, therefore, $Tl_2O_3+4Tl+3H_2O \rightleftharpoons 6Tl^{\cdot}+6OH'$, and the e.m.f. is given by $E=E_0-RT/4F \log C^6Tl^{\cdot}C^6OH'$. The experimental results agree satisfactorily with the calculation. The e.m.f. of the cells of the **thallium accumulator** used lies between 0·55 and 0·65 volt, and the capacity per kilogram is no greater than that of the lead accumulator. J. Regnauld measured the e.m.f. of the cell Zn | $ZnSO_4$, Tl_2SO_4 | Tl. W. Ostwald gave 10 Cals. per valence for the **heat of ionization.** K. Fajans and M. Born calculated the vol. and heat of ionization of Tl·-ions. K. G. Falk found the **transport number** of the cation in thallous sulphate soln. to be 0·479, and W. A. Bain, 0·472; and A. A. Noyes and K. G. Falk gave 7·60 units for the **speed of migration** of the cation at 25°.

W. J. Müller examined the anodic polarization of thallium in $\frac{1}{10}N$-sodium hydroxide, the current increases regularly with the polarization, and thallium dissolves in the univalent form up to an applied e.m.f. of 10 volts. With the anode in N-sodium hydroxide, there are three points on the polarization-strength of current curve at which the polarization remains practically constant with increased current, the first, at −0·7 volt, represents the dissolution of thallium in the univalent form; the second, at ±0 volt, probably represents the dissolution in the bivalent form; the third, at +1·1 volt, has not been fully investigated. When the polarized oxidized electrode is allowed to discharge, halts are observed at −0·3 and −0·6 volt. When the applied e.m.f. in $\frac{1}{10}N$-sulphuric acid is gradually raised, a point is reached at which the current remains practically constant on further increasing the e.m.f., and pulsations occur. The current in these circumstances is proportional to the surface of the electrode, and stirring increases it considerably. The explanation advanced is that thallous sulphate forms on the anode, and gives rise to a considerable resistance, but as it diffuses away, it allows the current to pass. Stirring naturally accelerates the diffusion of the salt, and thus increases the current. In both N- and N/10-sulphuric acid with larger applied e.m.f., abnormal polarization occurs, so that thallium shows two different states of **passivity.** In the former soln., yellow crystals are formed on the anode, which probably represent a mixture of thallous and thallic sulphate. Complicated phenomena also occur when sodium sulphate is used as electrolyte.

§ 4. The Chemical Properties of Thallium

> Le thallium est destiné à faire époque dans l'histoire de la chimie par l'étonnant contraste qui se manifeste entre ses caractères chimiques et ses propriétés physiques. Il n'y a pas d'exagération à dire qu'au point de vue de la classification généralement acceptée pour les métaux, le thallium offre une réunion de propriétés contradictoires qui autoriserait à l'appeler le métal paradoxal, l'ornithorrhynque des métaux. – J. B. A. DUMAS.[1]

Thallium forms two series of salts—thallous and thallic compounds—in which the element is respectively uni- and ter-valent. The general properties of the two series are very different. In the early days there were difficulties in assigning thallium a place in a particular family of elements. W. Crookes' premise that it belonged to the sulphur family was soon abandoned. The physical properties of the metal—appearance, sp. gr., hardness, m.p., and electrical conductivity—were

found to be analogous with those of lead, so also were many of the chemical properties of the salts of univalent thallium analogous with those of bivalent lead—e.g. the sparing solubility and colour of the thallous halides, and chromate, and the behaviour of the aq. soln. towards zinc are also analogous to the corresponding lead salts. The differences in valency, etc., however, were too pronounced to allow thallium to be included with the lead family of elements. Univalent thallium resembles the alkali metals in the flame spectra; the ready oxidation of the metal in air, the solubility of the hydroxide, sulphate, and carbonate in water; the existence of thallia-alums, and thallium chloroplatinate; and the isomorphism of its salts with those of potassium, rubidium, and cæsium. C. F. Rammelsberg, and G. N. Wyrouboff investigated the isomorphism of the sulphates, alums, phosphates, and tartrates; A. Fock, the dithionates; H. W. B. Roozeboom, the chlorates; H. E. Roscoe, the perchlorates; and J. W. Retgers, and C. van Eyk, the nitrates. Here again the differences were too marked to permit thallium being included with the family of alkali metals. Tervalent thallium has analogies with the aluminium family, it has but a small tendency to form alums; and in the low stability of the chloride and its tendency to form complexes, it resembles gold. D. I. Mendeléeff, in introducing the periodic classification, argued strongly in favour of including thallium with the aluminium family. He showed that in arranging the elements in the order of their at. wt., aluminium comes between magnesium and silicon, and thallium between mercury and lead. Just as the higher oxide of mercury is alone analogous with magnesium oxide, so does the highest oxide of lead show an analogy with silica, and the highest oxide of thallium show an analogy with alumina. Magnesium and mercuric oxides are strongly basic, aluminium and thallic oxides are feebly basic, while lead and silicon dioxides are feebly acidic. Lead, thallium, and mercury form a basic oxide lower than plumbic and mercuric oxides, while silicon, aluminium, and magnesium do not form well-defined lower oxides. The higher oxides HgO, Tl_2O_3, and PbO_2 are peroxidic relative to the lower oxides Hg_2O, Tl_2O, and PbO, and give off oxygen when heated; the higher chloride of mercury is stable, that of thallium unstable, and that of lead very unstable.

Thallium does not form any compound with **hydrogen.** A. Sieverts,[2] and D. P. Smith found that the quantity of gaseous hydrogen occluded by thallium can scarcely be detected, although, as T. W. Richards and C. P. Smyth pointed out, hydrogen formed at the cathode during electrolysis might be occluded to a greater extent as is the case with iron. L. Troost and P. Hautefeuille detected no analogy with the alkali metals in the tendency of thallium to form hydrides. Only a few c.c. are absorbed by the metal at 500° and 760 mm. press. W. B. Herapath assumed that a *thallium hydride* was formed which burnt with a green-coloured flame, but W. Crookes could not confirm this observation in the action of acids on zinc in the presence of thallium salts, or in the action of acids on a zinc-thallium alloy. When hydrogen is passed over red-hot thallium, the gas may carry along fine particles of the metal which colour the flame of the burning gas.

When a freshly cut surface is exposed to **air,** A. Lamy noted that it is gradually covered by a dark grey film which protects the metal from further change; at 100°, the metal rapidly becomes brown, but regains its lustre when dipped in water owing to the dissolution of the oxide. G. Gore said that attack by air is very slow in the cold, and rapid at 100°. C. F. Schönbein found that thallium is not changed at ordinary temp. in dry **oxygen,** and in thoroughly dried **ozone,** also, no change is perceptible, but in the presence of moisture, a brown film of oxide is immediately formed. A. Lamy found that when melted in oxygen, the metal inflames and becomes incandescent. According to J. B. A. Dumas, below a red heat the metal oxidizes, forming thallic oxide; at a red heat, a mixture of crystalline thallic and thallous oxide alone is formed. W. Crookes, A. Lamy, and E. J. Chapman noted that when heated above its m.p. in air, thallium gives brown fumes. W. Crookes said that when the moist metal is exposed to air, crystals of thallium carbonate are formed. A. Lamy found that **water** alone at ordinary temp. does not act on thallium, nor does the metal decompose boiling water; but W. Crookes found that the red-hot metal decomposes steam. C. Weltzien, and G. Wyrouboff said a mixture of thallous and thallic hydroxides are simultaneously formed: $2Tl+4H_2O=TlOH+Tl(OH)_3+2H_2$. R. Böttger noted that the metal is attacked by water with dissolved air, forming a mixture of thallous hydroxide and carbonate; and added that thallium is best preserved under water which has been well boiled, under an aq. soln. of glycerol, or under a soln. of thallous carbonate. J. Schiel recommended keeping the metal under water in which some drops of petroleum had been shaken. A. Kölliker emphasized the rapid oxidation (and dissolution) of thallium in aerated water. According to C. F. Schönbein, **hydrogen peroxide** produces a brown crust of thallic hydroxide which is later reduced to thallous hydroxide with the evolution of oxygen; K. Birnbaum also studied this reaction.

H. Moissan found that **fluorine** acts on thallium so vigorously that the metal becomes incandescent; A. Lamy, that thallium is attacked when heated in **chlorine** gas, and V. Thomas, that dried liquid chlorine has very little action on the metal. A. Lamy found that thallium unites with **bromine,** and, added J. Nicklès, the action is faster in the presence of water or alcohol. W. Crookes noted that **iodine** unites with heated thallium. R. Lepsius found that when thallium is heated in a stream of **hydrogen chloride,** hydrogen is evolved and thallous chloride formed. According to F. Kuhlmann, **hydrochloric acid,** and the halide acids, attack thallium with difficulty owing to the sparing solubility of the thallium halide, but **hydrofluoric acid,** which forms a readily soluble fluoride, attacks the metal tardly. W. Crookes found that aq. **chloric acid** dissolves thallium, forming thallous chlorate; and H. E. Roscoe found that **perchloric acid** likewise attacks the metal, forming thallous perchlorate.

According to W. Crookes, and A. Lamy, when thallium is melted with **sulphur, selenium,** or **tellurium,** the elements unite chemically. H. Pelabon has studied the union of thallium with sulphur, selenium, and tellurium. A. Röhrig found warm **sulphurous acid** attacks thallium very slowly, forming thallous sulphite. W. Crookes, and A. Lamy found thallium dissolves in **sulphuric acid,** forming thallous sulphate. W. O. Rabe showed that the dil. acid acts slowly, while the conc. acid acts more rapidly. According to A. Ditte, thallium dissolves in dil. sulphuric acid at a low temp. with the evolution of hydrogen, while the conc. acid forms sulphur dioxide, hydrogen sulphide, and free sulphur. F. W. Clarke stated that boiling **telluric acid** does not attack thallium. P. Nicolardot found thallium is not attacked by boiling **sulphur chloride,** S_2Cl_2—presumably a protective layer of chloride is formed. H. G. Denham found that thallium is dissolved by a soln. of **thallous sulphate,** and he assumed that a subsulphate is formed.

H. Flemming said that **nitrogen** does not unite directly with thallium; and F. H. Newman observed no absorption of this gas by thallium on the cathode of a discharge tube. C. A. Seely also found that liquid **ammonia** is without action; and R. Weber, that **nitrogen pentoxide** has no action. E. Carstanjen found that thallium is more readily attacked by **nitric acid** than by the other mineral acids, and with dil. nitric acid, hydrogen is evolved. W. Crookes showed that thallous nitrate is the main product, but if an excess of conc. nitric acid is used, much thallic nitrate is formed; while J. J. Acworth and H. E. Armstrong found that with dil. nitric acid (1 : 2), at 30°, the evolved gas contains 69·78 per cent. of nitric oxide, 19·15 per cent. of nitrous oxide, and 11·07 per cent. of nitrogen. With warm aqua regia, G. Werther, and E. Willm noted that thallic chloride is formed. J. J. Sudborough noted the formation of a complex, $TlCl.TlCl_3.2NOCl$, when thallium and **nitrosyl chloride** are heated in a sealed tube to 100°.

According to E. Carstanjen, **phosphorus** does not act on thallium when the two elements are melted together; but H. Flemming found that when phosphorus vapour is passed over molten thallium, a thin dark-coloured crust of possibly thallium phosphide is formed. E. Carstanjen found that thallium and **arsenic** or **antimony,** or **bismuth** readily alloy when melted together. Q. A. Mansuri obtained the f.p.

curves shown in Fig. 2 for binary alloys of arsenic and thallium. The two elements do not act on one another chemically, nor do they form solid soln. There is a eutectic at 215° with 8·01 per cent. of arsenic; with increase of arsenic the f.p. of the alloys rise to 240°. Alloys with 13 to about 40 per cent. of arsenic begin to freeze at 240° and form two layers—the upper one being rich in arsenic, and the lower one rich in thallium; with over about 40 per cent. of arsenic, the two layers disappear, and the soln. becomes uniform. R. S. Williams obtained the f.p. curve shown in Fig. 3 for binary alloys of thallium and antimony. There is evidence of the formation of the *thallium tritaantimonide*, Tl_3Sb. R. Kremann and A. Lobinger measured the e.m.f. of the thallium-antimony alloys, and found no indication of a compound. M. Chikashigé likewise obtained with thallium-bismuth alloys, Fig. 4, evidence of the formation of the *thallium tritapentabismuthide*, Bi_5Tl_3, and less decisive evidence with respect to *thallium tritabismuthide*, $BiTl_3$. R. Kremann and A. Lobinger found the e.m.f. behaviour indicated the existence of the compounds Bi_5Tl_3 and $BiTl_3$. N. S. Kurnakoff and co-workers found no evidence of the compound Bi_5Tl_3. N. S. Kurnakoff and N. A. Puschin, and C. T. Heycock and F. H. Neville studied the fusion curve of mixtures of these elements; D. Omodei, the thermal expansion.

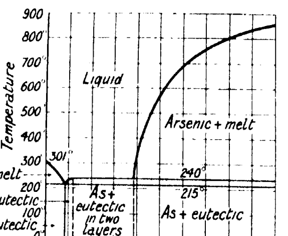

FIG. 2.—Freezing-point Curves of Alloys of Thallium and Arsenic.

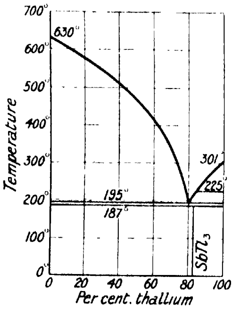

FIG. 3.—Freezing-point Curve of Thallium-Antimony Alloys.

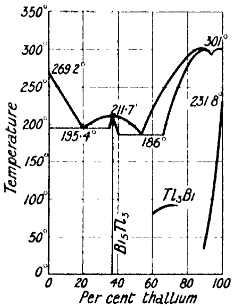

FIG. 4.—Freezing-point Curve of Thallium-Bismuth Alloys.

According to H. Moissan, **carbon, boron,** or **silicon** does not dissolve to an appreciable extent in thallium, nor do the two elements unite directly. H. Flemming said that thallium does not unite with **carbon dioxide** even if the temp. be raised to the softening point of glass. **Organic acids** attack thallium with difficulty. Thallium is covered by a dark crust when placed in **petroleum**; likewise also in **benzene,** and at the same time the liquid becomes turbid; in **chloroform,** dirty yellow flocks separate; absolute **methyl, ethyl, or isobutyl alcohol,** according to T. Svedberg, takes up appreciable quantities of thallium in a short time. R. Böttger found thallium is quickly attacked by neutral **methyl ether** free from alcohol; and in **ethyl ether** a yellowish-brown powder is formed and the liquid becomes turbid. J. F. Spencer and M. L. Wallace found that boiling **α-bromonaphthalene** forms thallic bromide; and boiling **iodobenzene,** thallous iodide. J. L. Sammis found a soln. of **cupric oleate** in pyridine does not attack thallium. A. Korczynsky studied the catalytic action of thallium and its salts on the hydrogenation of aromatic hydrocarbons. Thallium was found by W. C. Reid to precipitate the metal from soln. of **copper, silver, gold, mercury,** and **lead.** W. Crookes said that a soln. of **potassium permanganate** is reduced by thallium at ordinary temp.

The **physiological action** of thallium and its salts has been discussed by W. Crookes,[3] A. Lamy, J. J. Paulet, L. Grandeau, E. Jeanselme, H. Castex, J. Blake, H. Erdmann, A. Curci, B. Stadion, W. Luck, etc. The **uses** of thallium are not important. Any advantages offered by thallium or its compounds are counterbalanced by the cost. The chromate is stated by T. W. Salter[4] to furnish a richer yellow pigment than lead chromate. A. Lamy, and O. Schott say that if lead in glasses be replaced by thallium the product has a higher refractive index, and is better suited for the preparation of imitations of gem-stones. J. Gädicke and A. Miethe, and L. Vanino and co-workers recommend it in magnesium, etc., for increasing the luminosity. G. Meyer, H. Kreusler, and A. Hantzsch and W. H. Glover used the flame coloured with thallium as a source of monochromatic light. Thallous salts have also been recommended in testing for ozone; in the separation of chlorides and iodides (V. Thomas, and P. Jannasch and K. Aschoff); and in some microscopic tests (H. Behrens).

Reactions of analytical interest.—The thallous salts are colourless and usually soluble in water, although the chloride, bromide, iodide, sulphide, and chromate are but sparingly soluble. Thallic salts are readily reduced to thallous salts, and when an aq. soln. of thallic sulphate or nitrate is boiled, thallic hydroxide is precipitated. With **hydrochloric acid,** and soluble chlorides, thallous salts, in not too dil. a soln., give a white precipitate of thallous chloride which is slightly soluble in water, but less soluble in water containing a little hydrochloric acid. Thallic salts under similar conditions give no precipitate. H. Behrens[5] detected 0·00016 mgrm. of thallium by using this reaction as a microscopic test. With **potassium iodide,** yellow thallous iodide is formed even with dil. soln., and this is considered to be a very sensitive test for thallium. Unlike lead iodide, thallous iodide dissolves but sparingly in a cold soln. of sodium thiosulphate. According to H. Behrens, 0·0003 mgrm. can be detected by using this reaction as a microscopic test. Thallic salts give a brown precipitate which is a mixture of thallic and thallous iodides. F. Ephraim found that with a mixture of potassium iodide and antimony chloride, orange-red thallous iodoantimonite, $3TlI.2SbI_3$, separates. When **hydrogen sulphide** is passed into a soln. of thallous sulphate, acidified with mineral acids, no precipitation occurs, but with neutral soln., black thallous sulphide, Tl_2S, is incompletely precipitated. If arsenic, antimony, or copper salts be present, thallous sulphide is precipitated with the sulphides of those metals. With soln. acidified with acetic acid, the precipitation is complete. Thallous sulphide is readily dissolved by mineral acids; it is insoluble in acetic acid and alkaline sulphides; and it is readily oxidized to thallous sulphate when exposed to air. It is but slightly attacked by acetic acid. The precipitate is not soluble in aq. ammonia, alkali or ammonium sulphide, or potassium sulphide. When heated, the thallous sulphide first melts and then volatilizes. Thallic salt soln. behave in a similar manner towards hydrogen sulphide. Thallium salts give with **ammonium sulphide,** $(NH_4)_2S$, a precipitate of thallous sulphide. Similar results are obtained with hydrogen sulphide in alkaline soln.

Thallous salt soln. give no precipitate when treated with aq. **ammonia,** or **alkali hydroxides,** but thallic salts give brown thallic hydroxide, which changes to $TlO(OH)$ when exposed to air. The precipitate dissolves very slowly in acids, and is not soluble in an excess of alkali-lye. The presence of tartaric acid hinders the precipitation. Thallous carbonate is fairly soluble in water, so that **alkali carbonates** precipitate thallous carbonate only from conc. soln.; with thallic salts, thallic hydroxide is precipitated. Soln. of **alkali chromates** precipitate yellow thallous chromate—soluble in cold nitric or sulphuric acids—from soln. of thallous salts; and no precipitate with soln. of thallic salts. With not too dil. soln. of thallous salts, **hydrochloroplatinic acid** precipitates pale yellow thallous chloroplatinate,

Tl_2PtCl_6; H. Behrens claimed to detect 0·000008 mgrm. of thallium by this reagent used as a micro-test. *A white crystalline precipitate soluble in boiling water is formed when* **potassium thiocyanate** *is added to a soln. of a thallous salt. A soln. of* **sodium thiosulphate** *gives a white precipitate with thallous salt soln., the precipitate is soluble in boiling water, and when an acid is added to the soln., thallous sulphide is precipitated. Neutral soln. of thallous salts give a precipitate of thallic oxide with* **potassium permanganate**; *in acid soln., the thallous salt is oxidized to a thallic salt. Thallous sulphate, when treated with* **aluminium sulphate,** *gives colourless octahedral crystals of thallia alum,* $TlAl(SO_4)_2.12H_2O$. *According to M. Cunningham and F. M. Perkin, and S. M. Tanatar and S. Petroff, a pale red, sparingly soluble precipitate is produced when* **sodium cobaltinitrite** *is added to a thallous salt soln. According to L. Marino,* small quantities of thallic salts in the presence of thallous salts can be detected by the production of a blue coloration with **α-naphthol** and **dimethyl-p-phenylene-diamine. Zinc, aluminium** and **magnesium** precipitate black crystals of thallium from soln. of thallium salts.

The atomic weight of thallium.—Thallium has a hydrogen eq. of about 204 in thallous salts, and 68 in thallic salts. The at. wt. approaching 204 is in accord with the vapour density of the halide, and with the mol. wt. of the salts in soln. It is also in accord with sp. ht. rule; with the isomorphic rule in connection with the alums; and with the periodic scheme of classification. In 1862, A. Lamy[6] analyzed thallous sulphate, and from the ratio $Tl_2SO_4 : BaSO_4$, he calculated the at. wt. 205·22; and M. Hebberling from the same ratio obtained 204·97. A. Lamy analyzed thallous chloride, and from the ratio $TlCl : AgCl$ obtained 203·87; M. Hebberling from a similar ratio obtained 203·22; and H. L. Wells and S. L. Penfield, 204·48. G. Werther analyzed thallous iodide, and from the ratio $TlI : AgI$, obtained 203·81. W. Crookes converted thallium into the nitrate, and from the ratio $Tl : TlNO_3$ obtained 204·04(N = 14·01). C. Lepierre, from the ratio $Tl_2O_3 : 2Tl$ obtained 204·14; from $Tl_2O_3 : 2Tl$, 204·16; from $2TlNO_3 : Tl_2O_3$, 204·04 (N=14·01), $Tl_2SO_4 : Tl_2O_3$, 203·99; and from $Tl_2O_3 : 3H_2O$, 204·29. A study of the different ratios gave F. W. Clarke 204·04; B. Brauner, 204; and the International Table for 1922, 204·0. The **atomic number** is 81. F. W. Aston[7] attempted to find the **isotopes** of thallium, but was not successful. W. P. Jorissen and J. A. Vollgraff did not succeed in producing thallium from bismuth by the action of the cathode rays, although they found that bismuth commonly contains a trace of thallium.

§ 5. The Alloys of Thallium

A. Lamy[1] found that thallium readily alloys with many metals. E. Carstanjen obtained alloys of thallium with potassium, sodium, magnesium, zinc, cadmium, mercury, aluminium, tin, lead, antimony, and bismuth; most of these were not very stable in air, and E. J. Chapman obtained brittle alloys with gold, antimony, bismuth, and platinum; malleable alloys with copper, silver, and lead; and an easily oxidized alloy with tin. E. Carstanjen found that sodium and thallium unite without incandescence when the elements are melted together; potassium and thallium behave similarly but become feebly incandescent. The alloys are crystalline and silver-white. The f.p. curves of thallium with each of these elements are shown in Figs. 5 and 6. With sodium, there is a eutectic with the ratio Tl : Na=1 : 12·89 at 64·1°; a break with the ratio 1 : 6·11 at 77·9°—possibly owing to the formation of *hexasodium thallide*, Na_6Tl; a break with the ratio 1 : 2·37 at 153·7°—owing to the formation of **sodium hemithallide,** Na_2Tl; a distectic point or maximum with the ratio 1 : 1 at 306·8°—owing to the formation of **sodium thallide,** NaTl; and a eutectic with the ratio 1·73 : 1 at 237·7°. R. Kremann and P. von Reiningshaus studied the e.m.f. of alloys of sodium and thallium in cells Tl | N-Na_2SO_4 | $Tl_{1-n}Na_n$, and found evidence of NaTl, but not of Na_2Tl or of

Na_5Tl. The f.p. curve with potassium has a transition point with the ratio Tl : K=1 : 2·03 at 242·2°—corresponding with **potassium hemithallide,** K_2Tl; a diatectic point or maximum when the ratio is 1 : 1, at 335°—corresponding with **potassium thallide,** KTl, and a eutectic with the ratio 6·31 : 1 at 172·5°.

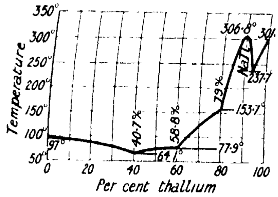

Fig. 5.—Freezing Points of Alloys of Thallium and Sodium.

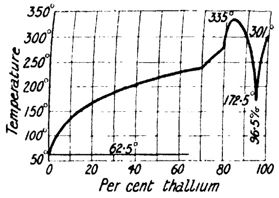

Fig. 6.—Freezing Points of Alloys of Thallium and Potassium.

E. Carstanjen found the alloys readily oxidize in air; and they dissolve violently in water giving off hydrogen. They can be preserved under petroleum. C. T. Heycock and F. H. Neville found that thallium readily dissolves in molten sodium and a gram-atom of thallium in 100 gram-atoms of sodium lowers the m.p. 4·12°–4·72°. R. Kremann and E. Pressfreund studied the e.m.f. of the thallium-potassium alloys, as in the case of the sodium alloys.

W. Crookes found that when thallium is melted with *copper* much of the former is volatilized. E. Carstanjen melted the two elements under borax. F. Doerinckel observed the formation of no compounds or mixed crystals, Fig. 7. The two elements are only partially miscible; at 959° (the m.p. of copper) the layer rich in copper contains 35·1 per cent. by weight of thallium, the layer rich in the latter metal only 1·8 per cent. of copper. The eutectic point of the alloy rich in thallium lies at 302°, a little below the m.p. of thallium. W. Crookes said that the alloys with an excess of copper are golden yellow, those with an excess of thallium are white. E. Carstanjen said that sulphuric acid attacks only the thallium; nitric acid dissolves both constituents with the separation of thallium nitrate. W. Crookes prepared alloys of *silver* and thallium and found that they could be cupelled like silver-lead alloys. C. T. Heycock and F. H. Neville found the lowering of the f.p. of alloys with 0 to 20 per cent. of thallium is proportional to the conc. of the last-named metal. According to G. I. Petrenko, the f.p. curve of this system, Fig. 8, consists of two branches which meet in a eutectic point at 287°; the eutectic mixture contains 2·5 per cent. weight of silver. The m.p. of thallium is 303°–304°. The elements form only one series of mixed crystals which contain 0–10 per cent. by weight of thallium. A. L. Bernoulli measured the electrical resistance of these alloys, and

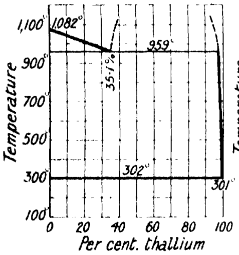

Fig. 7.—Freezing-point Curve of Alloys of Copper and Thallium.

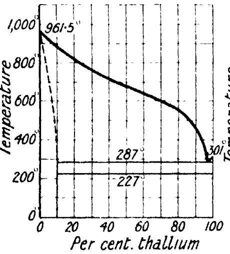

Fig. 8.—Freezing-point Curve of Alloys of Silver and Thallium.

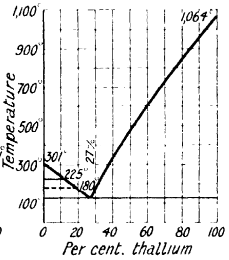

Fig. 9.—Freezing-point Curve of Alloys of Gold and Thallium.

their thermoelectric force against copper; C. Hardebeck, and R. Schenck compared the electrical and thermal conductivity of silver-thallium alloys. M. Levin detected no compounds of *gold* and thallium in his study of the f.p. curve, Fig. 9, of these alloys. He found that the f.p. of both gold and thallium are lowered by the addition of the other metal; the two branches of the f.p. curve intersect at a eutectic point corresponding with a temp. of 131° and with 27 per cent. of thallium. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of thallium by gold. F. Osmond and W. C. Roberts-Austen measured the tensile strength of these alloys.

L. Donsky studied alloys of thallium with up to 15 per cent. of *calcium*. He found that the eutectic temp. lies about 6° higher than the m.p. of thallium, from which the conclusion is drawn that mixed crystals rich in calcium are present; at the eutectic temp. these are in equilibrium with **calcium trithallide,** $CaTl_3$, and the fused matrix. Between 6 per cent. and 16 per cent. of calcium, **calcium thallide,** CaTl (needles), separates; at 524° this compound reacts with the fused mass to form $CaTl_3$ (bluish crystals), which separate primarily from about 0·5 6 per cent. of calcium. The alloys are harder than thallium, brittle, and oxidize rapidly in the air. Those containing more than 6 per cent. of calcium do not decompose water at the ordinary temp. N. Baar found that calcium and thallium also form **calcium tetratritathallide,** Ca_3Tl_4, at 555°, Fig. 10; he also found evidence of $CaTl_4$ at 524°, and CaTl at 969°. There is a eutectic at 692° with 38 per cent. of calcium, and a limited number of solid soln. are formed, so that the transformation point of thallium is raised by the addition of calcium. G. Tammann studied the chemical activity of these alloys.

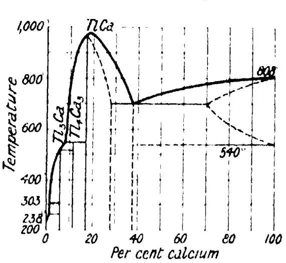

Fig. 10.—Freezing-point Curve of Alloys of Calcium and Thallium.

According to S. Mellor,[2] *magnesium* and thallium can be alloyed in any proportion; the alloy with 5 per cent. of thallium is more malleable than magnesium; and the alloys rich in thallium oxidize readily. E. Carstanjen made wire from an alloy of equal parts of the two metals. According to G. Grube, with addition of thallium the m.p. of magnesium, Fig. 11, falls to a eutectic point corresponding with 405° and 72·5 per cent. of thallium. It next rises to a maximum at 76 per cent. and 412·9°. From this maximum it falls to a second eutectic point at 392·9° and 84·8 per cent. of thallium, and then to further eutectic points at 355·4° and 89·3 per cent. of thallium and at 205·2° and 97·1 per cent. of thallium, and finally rises to the m.p. of thallium. From the course of the curve, with its sharp maximum and two concealed maxima, the existence of three compounds is inferred, namely, **octomagnesium trithallide,** Tl_3Mg_8, **magnesium hemithallide,** $TlMg_2$, and **magnesium ditritathallide,** Tl_2Mg_3. Tl_3Mg_8 melts at 412·9° to a homogeneous liquid. $TlMg_2$ undergoes transformation at 392·9° in accordance with the equation $TlMg_2 \rightleftharpoons 0·0796 Tl_3Mg_8 +$ fused alloy (0·9204 Tl + 1·9204 Mg). Tl_2Mg_3 has a transformation point at 355·4°: $Tl_2Mg_3 \rightleftharpoons 0·1194 TlMg_3 +$ fused alloy (1·8806 Tl + 2·8806 Mg). Thallium-magnesium alloys blacken in the air by oxidation, especially in presence of moisture. S. Mellor found the alloys burn more vigorously and more slowly than magnesium alone. E. Carstanjen prepared alloys of *zinc and thallium*. According to A. von Vegesack, the two metals have only a limited miscibility, Fig. 12. At its m.p., zinc dissolves about 2·5 per cent. of thallium, and the m.p. of zinc is then lowered about 3°; at its m.p., thallium dissolves about 5 per cent. of zinc, and its m.p. lowered about 4°. No chemical compounds or mixed crystals were observed. C. T. Heycock and F. H. Neville found one atomic per cent. of thallium in zinc lowered the f.p. 5·1°. C. di Capua measured the hardness of these alloys. E. Carstanjen found the alloys to be readily soluble in sulphuric acid with the evolution of hydrogen. R. Kremann and A. Lobinger studied the e.m.f. of thallium-zinc alloys; A. Matthiessen and C. Vogt, the electrical conductivity; and D. Omodei, the thermal expansion. E. Carstanjen also prepared *thallium-cadmium* alloys; and N. S. Kurnakoff and N. A. Puschin found the f.p. curve is of the simple V-type with the eutectic at 203·5° and with the atomic proportion Cd : Tl=1 : 2·67, *i.e.* 81·7 per cent. of thallium, Fig. 13. C. di Capua also studied the hardness and other properties of cadmium-thallium alloys; A. W. Smith, the thermal conductivity; and R. Kremann and A. Lobinger, their e.m.f., and no sign of a compound of thallium with zinc or cadmium was observed. E. Carstanjen prepared ternary Tl—Cd—Bi alloys; and C. F. Heycock and F. H. Neville, Tl—Cd—Ag, and Tl—Cd—Au alloys.

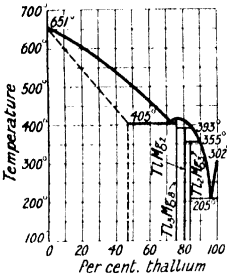

FIG. 11.—Freezing-point Curve of Alloys of Magnesium and Thallium.

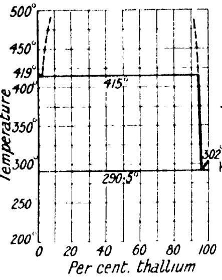

FIG. 12.—Freezing-point Curve of Alloys of Zinc and Thallium.

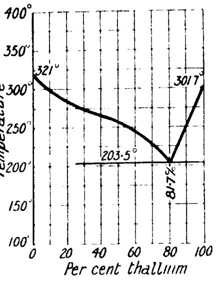

FIG. 13.—Freezing-point Curve of Alloys of Cadmium and Thallium.

W. Crookes[3] obtained crystalline **thallium amalgams.** Thallium was shown by J. Nicklès to amalgamate with mercury. W. Ramsay, J. Regnauld, A. Sucheni, K. Bornemann and G. von Rauschenplat, etc., prepared alloys by direct union of the metals; and T. W. Richards and J. H. Wilson, by electrolysis with a mercury cathode of a soln. of thallous sulphate in the presence of ammonium oxalate to prevent the formation of peroxides at the anode. P. Pavlovitsch, and N. S. Kurnakoff and N. A. Puschin measured the f.p. curve of thallium amalgams. The curve drops, Fig. 14, from the f.p. of mercury −39° to a eutectic at −60° with 8·5 at. per cent. of thallium; it then rises to a maximum at 15° with 33·3 at. per cent. of thallium corresponding with **mercury hemithallide,** Hg_2Tl; there is another eutectic at 3·5° and 40 at. per cent. of thallium; the curve then rises steadily to the m.p. of thallium. The curve, Fig. 14, has been revised by G. D. Roos. P. Pavlovitsch, and L. Rolla said that the maximum on the f.p.-composition curve does not correspond with a definite compound. C. H. Desch found the rules of A. Gorboff, and F. M. Flawitzky to have only a limited application. J. H. Hildebrand's vap. press. determinations suggested the possible existence of *mercury hexitathallide*, Hg_6Tl; the existence of J. Regnauld's Hg_5Tl, and Hg_5Tl_2, and E. Carstanjen's $HgTl_2$ have not been confirmed; they were made by alloying the two metals in the requisite proportions. A. Sucheni, N. S. Kurnakoff and N. A. Puschin, and K. Bornemann made observations on this subject. W. J. Humphreys studied the diffusion of thallium in mercury. L. Rolla found that the hardness-composition curve is continuous; and T. W. Richards and C. P. Smyth found that the hardness of solid thallium amalgams increased until 5 per cent. of mercury

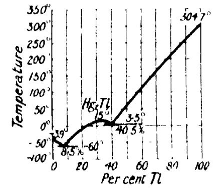

FIG. 14.—Freezing-point Curve of Alloys of Thallium and Mercury.

had been added, further additions of mercury softened the amalgam; they also found that the sp. gr. of solid thallium amalgams indicate an increase in volume during amalgamation; and the curve shows a slight inflexion at about 5 per cent. of mercury. H. Feninger measured the viscosity of the amalgams; and F. Schmidt, the surface tension. T. W. Richards and co-workers obtained for the heat of soln., Q joules per gram-atom of thallium in amalgam, when p per cent. of thallium was present.

G. N. Lewis and M. Randall calculated values for this constant from the data of T. W. Richards and F. Daniels. P. Pavlovitsch found a break in the electrolytic potential-composition curve at 27 to 28 at. per cent. of thallium, and it was thought to represent a compound Hg_3Tl, which forms solid soln. with both components. T. W. Richards and J. H. Wilson found 13·504, 13·515, and 13·527 for the sp. gr. of amalgams with 1·854, 1·410, and 0·793 per cent. of thallium at 20°. L. Rolla found the sp. vol. to be those calculated for mixtures, and to give no evidence of chemical combination. W. Ramsay studied the lowering of the vap. press. of mercury by thallium, and hence deduced an at. wt. 204·2. E. Beckmann and O. Liesche observed the raising of the b.p. of mercury by thallium. J. H. Hildebrand and E. D. Eastman studied the vap. press., and heat of dilution; D. MacIntosh and F. M. G. Johnson recommended 5 per cent. thallium amalgam as a liquid for thermometers down to −60°. G Tammann measured the lowering of the f.p. of mercury by thallium. R. H. Gerke studied the free energy of the thallium amalgams, and found −51 cals. per gram for the thallium, and −523 cals. per gram for the mercury. H. Feninger, K. Bornemann and G. von Rauschenplat measured the electrical conductivity and resistance of the amalgams. P. Pavlovitsch found the electrical conductivity appears as a maximum with amalgams having 26 to 28 at. per cent. of thallium. J. F. Spencer, A. Sucheni G. Mayr, V. Rothmund, and T. W. Richards and co-workers measured the potential difference of soln. of thallium salts and thallium amalgams, and G. N. Lewis and M. Randall applied the results to calculate various physical properties of thallium. For T. W. Richards and C. P. Smyth on the potential difference of thallium and thallium amalgams, *vide* thallium. J. Regnauld found thallium to be electronegative towards its amalgams. J. Nicklès found that thallium is dissolved from the amalgam by acidulated water.

E. Carstanjen[4] melted *aluminium and thallium* under borax and obtained what he regarded as an alloy of the two metals, but F. Doerinckel found that the two metals are not soluble in one another to any appreciable extent, Fig. 15; and they do not enter into chemical combination, or form mixed crystals. N. S. Kurnakoff and N. A. Puschin found that *thallium and indium* alloys give two f.p. curves which intersect at 180°, and 44·5 at. per cent. of thallium. There is a break near the transition point, 180°. Expressing the composition of the binary alloys in terms of the at. per cent. of indium:

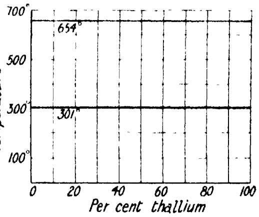

FIG. 15.—Freezing-point Curve of Alloys of Aluminium and Thallium.

In . .	100	95·88	73·72	61·30	50·25	37·87	25·51	12·23	0
F.p. .	154·0°	154·0°	158·6°	169·3°	216·3°	228·9°	256·5°	284·0°	301·0°

The one curve is convex to the conc.-axis and rises steadily from the m.p. of indium to 180° with 44·5 at. per cent. of thallium and represents solid soln. of thallium in indium (cubic system) with 0 to 48·5 at. per cent. of thallium. The other curve is concave to the conc.-axis, and represents solid soln. with from 44·5 to 100 per cent. of thallium; but there is a gap in the series between 48·5 and 56 at. per cent. of thallium. Alloys with 0 to 44·5 and 56–100 at. per cent. of thallium show one, *not two, arrest on the cooling curve.*

§ 6. Thallium Oxides

In his early observations, W. Crookes[1] assumed that a *thallium suboxide* can be prepared, but A. Lamy could not verify its existence, and W. Crookes himself did not mention it later. R. Lorenz suggested that the black film which forms on a thallium anode in potassium nitrate or sulphate soln. is a suboxide which, on further electrolysis, passes into thallic hydroxide. *Thallous oxide*, Tl_2O, and *thallic oxide*, Tl_2O_3, are well-defined basic oxides; there are in addition, an ill-defined intermediate oxide *thallosic oxide*, $Tl_2O.Tl_2O_3$, or TlO, and *thallic peroxide*, Tl_3O_5. In addition there are the hydrated compounds: *thallous hydroxide*, Tl(OH), *i.e.* $Tl_2O.H_2O$;

metathallic hydroxide, TlO.OH, *i.e.* $Tl_2O_3.H_2O$; and a doubtful *thallic hydroxide*, $Tl(OH)_3$, or $Tl_2O_3.3H_2O$.
